<b>Preface</b>	<b>xvii</b>
Compendium Introduction . . . . .	1
 <b>I The Implementation of the Icon Programming Language</b>	 <b>3</b>
<b>1 Introduction</b>	<b>7</b>
1.1 Implementing Programming Languages . . . . .	8
1.2 The Background for Icon . . . . .	9
 <b>2 Icon Language Overview</b>	 <b>11</b>
2.1 The Icon Programming Language . . . . .	12
2.1.1 Data Types . . . . .	12
2.1.2 Expression Evaluation . . . . .	14
2.1.3 Csets and Strings . . . . .	21
2.1.4 String Scanning . . . . .	23
2.1.5 Lists . . . . .	24
2.1.6 Sets . . . . .	26
2.1.7 Tables . . . . .	27
2.1.8 Records . . . . .	27
2.1.9 Input and Output . . . . .	28
2.1.10 Procedures . . . . .	28
2.1.11 Co-Expressions . . . . .	33
2.1.12 Diagnostic Facilities . . . . .	35
2.2 Language Features and the Implementation . . . . .	38
 <b>3 Organization of the Implementation</b>	 <b>41</b>
3.1 The Icon Virtual Machine . . . . .	42
3.2 Components of the Implementation . . . . .	42
3.3 The Translator . . . . .	43

3.4	The Linker	44
3.4.1	Scope Resolution	45
3.4.2	Construction of Run-Time Structures	45
3.5	The Run-Time System	45
<b>4</b>	<b>Values and Variables</b>	<b>49</b>
4.1	Descriptors	50
4.1.1	Strings	51
4.1.2	The Null Value	52
4.1.3	Integers	52
4.2	Blocks	53
4.3	Variables	54
4.3.1	Operations on Variables	55
4.3.2	Special Variables	56
4.3.2.1	Trapped Variables	56
4.3.2.2	Keyword Variables	57
4.4	Descriptors and Blocks in C	58
4.4.1	Descriptors	58
4.4.2	Blocks	59
4.4.3	Defined Constants	60
4.4.4	RTL Coding	62
<b>5</b>	<b>Strings and Csets</b>	<b>67</b>
5.1	Strings	68
5.1.1	Representation of Strings	68
5.1.2	Concatenation	69
5.1.3	Substrings	72
5.1.4	Assignment to Subscripted Strings	73
5.1.5	Mapping	75
5.2	Csets	79
<b>6</b>	<b>Lists</b>	<b>83</b>
6.1	Structures for Lists	83
6.2	Queue and Stack Access	87
6.3	Positional Access	95
6.4	Arrays (Unicon only)	98
<b>7</b>	<b>Sets and Tables</b>	<b>101</b>
7.1	Sets	102
7.1.1	Data Organization for Sets	102

7.1.2	Set Operations	104
7.2	Tables	105
7.2.1	Data Organization for Tables	105
7.3	Hashing Functions	108
<b>8</b>	<b>The Interpreter</b>	<b>117</b>
8.1	Stack-Based Evaluation	117
8.2	Virtual Machine Instructions	118
8.2.1	Constants	119
8.2.2	Identifiers	120
8.2.3	Operators	128
8.2.4	Functions	130
8.2.5	Self-Modifying Instructions	131
8.3	The Interpreter Proper	132
8.3.1	The Interpreter Loop	132
8.3.2	Interpreter State Variables	134
<b>9</b>	<b>Expression Evaluation</b>	<b>137</b>
9.1	Bounded Expressions	138
9.1.1	Expression Frames	140
9.2	Failure	142
9.3	Generators and Goal-Directed Evaluation	145
9.4	Generative Control Structures	158
9.4.1	Alternation	158
9.4.2	Repeated Alternation	160
9.4.3	Limitation	161
9.5	Iteration	162
9.6	String Scanning	163
<b>10</b>	<b>Functions, Procedures, and Co-Expressions</b>	<b>169</b>
10.1	Invocation Expressions	169
10.2	Procedure Blocks	170
10.3	Invocation	173
10.3.1	Argument Processing	173
10.3.2	Function Invocation	174
10.3.3	Procedure Invocation	177
10.4	Co-Expressions	179

<b>11</b>	<b>Storage Management</b>	<b>187</b>
11.1	Memory Layout . . . . .	189
11.2	Allocation . . . . .	192
11.2.1	The Static Region . . . . .	193
11.2.2	Blocks . . . . .	193
11.2.3	Strings . . . . .	193
11.3	Garbage Collection . . . . .	194
11.3.1	The Basis . . . . .	195
11.3.2	The Location Phase . . . . .	196
11.3.3	Pointer Adjustment and Compaction . . . . .	206
11.3.4	Collecting Co-Expression Blocks . . . . .	216
11.3.5	Multiple Regions . . . . .	217
11.3.6	Storage Requirements during Garbage Collection . . . . .	218
11.4	Predictive Need . . . . .	219
<b>12</b>	<b>Run-Time Support Operations</b>	<b>225</b>
12.1	Type Checking and Conversion . . . . .	225
12.2	Dereferencing and Assignment . . . . .	230
12.2.1	Dereferencing . . . . .	231
12.2.2	Assignment . . . . .	233
12.3	Input and Output . . . . .	239
12.3.1	Files . . . . .	239
12.3.2	Reading and Writing Data . . . . .	240
12.4	Diagnostic Facilities . . . . .	241
<b>II</b>	<b>An Optimizing Compiler for Icon</b>	<b>245</b>
	Preface to Part II . . . . .	248
<b>13</b>	<b>The Optimizing Compiler</b>	<b>249</b>
13.1	Motivation . . . . .	249
13.2	Type Inferencing . . . . .	250
13.3	Liveness Analysis . . . . .	251
13.4	Analyzing Goal-Directed Evaluation . . . . .	252
<b>14</b>	<b>The Translation Model</b>	<b>255</b>
14.1	Data Representation . . . . .	256
14.2	Intermediate Results . . . . .	256
14.3	Executable Code . . . . .	257

<b>15</b>	<b>The Type Inferencing Model</b>	<b>265</b>
15.1	Motivation . . . . .	265
15.2	Abstract Interpretation . . . . .	266
15.3	Collecting Semantics . . . . .	269
	Model 1: Eliminating Control Flow Information . . . . .	272
	Model 2: Decoupling Variables . . . . .	274
	Model 3: A Finite Type System . . . . .	277
<b>16</b>	<b>Liveness Analysis of Intermediate Values</b>	<b>281</b>
16.1	Implicit Loops . . . . .	282
16.2	Liveness Analysis . . . . .	283
16.3	An Attribute Grammar . . . . .	287
16.4	Primary Expressions . . . . .	288
16.5	Operations with Subexpressions . . . . .	289
16.6	Control Structures . . . . .	291
<b>17</b>	<b>Overview of the Compiler</b>	<b>295</b>
17.1	Components of the Compiler . . . . .	295
17.2	The Run-time System . . . . .	296
17.3	The Implementation Language . . . . .	297
17.4	Standard and Tailored Operation Implementations . . . . .	300
<b>18</b>	<b>Organization of Iconc</b>	<b>303</b>
18.1	Compiler Phases . . . . .	303
18.2	Naive Optimizations . . . . .	305
18.3	Code Generation for Procedures . . . . .	306
<b>19</b>	<b>The Implementation of Type Inferencing</b>	<b>307</b>
19.1	The Representation of Types and Stores . . . . .	307
19.2	A Full Type System . . . . .	308
19.3	Procedure Calls and Co-Expression Activations . . . . .	313
19.4	The Flow Graph and Type Computations . . . . .	315
<b>20</b>	<b>Code Generation</b>	<b>319</b>
20.1	Translating Icon Expressions . . . . .	322
20.2	Signal Handling . . . . .	326
20.3	Temporary Variable Allocation . . . . .	329

<b>21</b>	<b>Control Flow Optimizations</b>	<b>337</b>
21.1	Naive Code Generation . . . . .	337
21.2	Success Continuations . . . . .	338
21.3	Iconc's Peephole Optimizer . . . . .	340
<b>22</b>	<b>Optimizing Invocations</b>	<b>345</b>
22.1	Invocation of Procedures . . . . .	345
22.2	Invocation and In-lining of Built-in Operations . . . . .	346
22.3	Heuristic for Deciding to In-line . . . . .	348
22.4	In-lining Success Continuations . . . . .	349
22.5	Parameter Passing Optimizations . . . . .	351
22.6	Assignment Optimizations . . . . .	354
<b>23</b>	<b>Performance of Compiled Code</b>	<b>357</b>
23.1	Expression Optimizations . . . . .	357
23.2	Program Execution Speed . . . . .	360
23.3	Code Size . . . . .	362
<b>24</b>	<b>Scalable Type Inferencing</b>	<b>365</b>
24.1	The Type Representation . . . . .	366
24.2	Type Vector Hashing . . . . .	367
24.3	Type Inferencing . . . . .	367
24.4	A Copy-on-Write Type Vector Pool . . . . .	368
24.5	Implementation . . . . .	369
24.5.1	Bit Vector Hashing . . . . .	369
24.5.2	Hash Halving . . . . .	370
24.6	Metrics . . . . .	374
24.6.1	Space . . . . .	374
24.6.2	Time . . . . .	375
24.6.3	Measuring the Techniques . . . . .	376
24.6.4	Collision Rates . . . . .	377
24.7	Conclusions . . . . .	378
<b>25</b>	<b>Optimizing Code Generated by Iconc</b>	<b>381</b>
25.1	Areas Where Iconc Can Be Improved . . . . .	381
25.1.1	Redundant Function Calls . . . . .	382
25.1.2	Constant Propagation . . . . .	382
25.1.3	Variable Initialization . . . . .	382
25.2	Enabling Optimizations . . . . .	382
25.3	Intermediate Code Representation . . . . .	382

25.3.1	How Code is Generated	383
25.4	Redundant Function Calls	386
25.5	Icon Literals and Constant Propagation	387
25.5.1	Tended Descriptor Tables	387
25.5.2	Analyzing Literal Assignments	388
25.5.3	New Functions	392
25.6	Variable Initialization	394
25.6.1	Eliminating Dead Code	394
25.6.2	Loop Unrolling	394
25.7	Results	395
25.7.1	Execution Speed	396
25.7.2	Code Size	397
25.7.3	Analysis of Intermediate Code Optimizations	398
25.8	Conclusion and Future Optimizations	399
<b>26</b>	<b>Future Work on the Compiler</b>	<b>405</b>
26.1	Summary of Part II	405
26.2	Future Work	406
<b>III</b>	<b>The Implementation of Unicon</b>	<b>409</b>
<b>27</b>	<b>The Unicon Translator</b>	<b>413</b>
27.1	Overview	413
27.2	Lexical Analysis	413
27.2.1	Lex-compatible API	414
27.2.2	Character Categories	414
27.2.3	The Token Type	414
27.2.4	Error Handling and Debugging	414
27.2.5	Reserved Words	415
27.2.6	Big-inhale Input	415
27.2.7	Semicolon Insertion	416
27.2.8	The Real Lexical Analyzer Function, yylex2()	418
27.3	The Unicon Parser	420
27.3.1	Syntax Error Handling	422
27.4	The Unicon Preprocessor	422
27.5	Semantic Analysis	424
27.6	Object Oriented Facilities	429
27.6.1	Implementing Multiple Inheritance in Unicon	432

27.6.2	Unicon's Progend() revisited . . . . .	436
27.6.3	Other OOP Issues . . . . .	437
27.6.4	On Public Interfaces and Runtime Type Checking . . . . .	438
<b>28</b>	<b>Networking, Messaging and the POSIX Interface</b>	<b>439</b>
28.1	Networking Facilities . . . . .	439
28.1.1	Sockets in the Unicon File Functions . . . . .	439
28.1.2	Simultaneous Input from Different File Types . . . . .	439
28.2	Messaging Facilities . . . . .	440
28.2.1	The Transfer Protocol Library . . . . .	440
28.2.2	Libtp Architecture . . . . .	440
28.2.3	The Discipline . . . . .	440
28.2.4	Exception Handling . . . . .	441
<b>29</b>	<b>ODBC Database Facilities</b>	<b>445</b>
29.1	Organization . . . . .	445
29.2	ISQLFile type . . . . .	446
<b>30</b>	<b>Portable 2D and 3D Graphics</b>	<b>449</b>
30.1	Graphics Source Files Summary . . . . .	449
30.2	Structures Defined in graphics.h . . . . .	451
30.3	Platform Macros and Coding Conventions . . . . .	452
30.4	Window Manipulation in rxwin.ri and rmswin.ri . . . . .	452
30.4.1	Window Creation and Destruction . . . . .	453
30.4.2	Event Processing . . . . .	453
30.4.3	Resource Management . . . . .	454
30.4.4	Memory Management and r*rsc.ri Files . . . . .	454
30.4.5	Color Management . . . . .	454
30.4.6	Font Management . . . . .	455
30.5	External Image Files and Formats . . . . .	455
30.6	Implementation of 3D Facilities . . . . .	455
30.6.1	3D Facilities Requirements . . . . .	455
30.6.2	Files . . . . .	456
30.6.3	Redrawing Windows . . . . .	456
30.6.4	Textures . . . . .	456
30.6.5	Texture Coordinates . . . . .	457
30.7	Graphics Facilities Porting Reference . . . . .	458
30.8	The X Implementation . . . . .	468
30.9	The MS Windows Implementation . . . . .	468

30.9.1	Installing, Configuring, and Compiling the Source Code . . . . .	468
<b>31</b>	<b>The Uniconc Optimizing Unicon Compiler</b>	<b>471</b>
31.1	Overview . . . . .	471
31.2	Uniconc Organization . . . . .	472
31.3	Design Considerations . . . . .	472
31.4	Translation Model . . . . .	474
31.5	The UNICON <sup>Δ</sup> Subsystem . . . . .	475
31.5.1	Syntax Analysis . . . . .	475
31.5.2	Semantic Analysis . . . . .	479
31.5.3	Code Generation . . . . .	480
31.6	The ICONC <sup>Δ</sup> Subsystem . . . . .	480
31.6.1	Syntax Analysis . . . . .	480
31.6.2	Semantic Analysis . . . . .	483
31.6.3	Code Generation . . . . .	486
31.7	Optimizations In Compiled Targets . . . . .	486
31.7.1	Representation of Class Instances . . . . .	486
31.7.1.1	The Proposed Optimization . . . . .	491
31.7.1.2	Results . . . . .	492
31.7.2	Invocations . . . . .	492
31.7.2.1	Background . . . . .	495
31.7.2.2	The Proposed Optimization . . . . .	495
31.7.2.3	Results . . . . .	496
31.7.3	Dereferences . . . . .	498
31.7.3.1	Background . . . . .	498
31.7.3.2	The Proposed Optimization . . . . .	498
31.7.3.3	Results . . . . .	498
31.8	Metrics . . . . .	499
31.8.1	Overview . . . . .	499
31.8.2	Invocations . . . . .	499
31.8.3	Field References . . . . .	501
31.8.4	Space Savings In Compiled Targets . . . . .	501
31.8.5	General Programs . . . . .	502
31.9	Future Work . . . . .	504
31.9.1	Limitations . . . . .	504
31.9.1.1	Scalability . . . . .	505
31.9.1.2	Lack of Introspection . . . . .	506
31.9.1.3	Disambiguation . . . . .	507
31.9.2	Potential Improvements . . . . .	508

31.10 Conclusion . . . . .	509
<b>32 Concurrency and Thread-Safety</b>	<b>515</b>
32.1 Thread State . . . . .	516
32.2 Synchronization . . . . .	516
32.2.1 Critical Regions and Mutexes . . . . .	516
32.2.2 Condition Variables . . . . .	519
32.3 Thread Communication . . . . .	519
32.3.1 Thread messaging Queues . . . . .	520
32.3.2 Send and Receive Operators . . . . .	520
32.3.3 Inbox/Outbox and the Attrib() Function . . . . .	521
32.3.4 Blocking Send and Receive . . . . .	522
32.4 Virtual Machine Changes . . . . .	524
32.4.1 VM Registers . . . . .	524
32.4.2 Self-Modifying Instructions . . . . .	524
32.4.3 Runtime System Support . . . . .	525
32.4.3.1 Input/Output Sub-system . . . . .	525
32.4.3.2 C Library Thread Safety . . . . .	526
32.4.3.3 Allocation and Separate Heaps . . . . .	526
32.4.4 Garbage Collection . . . . .	527
<b>33 Execution Monitoring</b>	<b>529</b>
33.1 Dynamic Loading and the Program State . . . . .	529
33.2 Event Instrumentation, Filtering and Reporting . . . . .	534
33.2.1 Filtering: Event Masks and Value Masks . . . . .	534
33.3 Instrumented vs. Uninstrumented Run-time Functions . . . . .	536
 <b>IV Appendices</b>	 <b>539</b>
<b>A Data Structures</b>	<b>541</b>
A.1 Descriptors . . . . .	541
A.1.1 Values . . . . .	541
A.1.2 Variables . . . . .	542
A.2 Blocks . . . . .	542
A.2.1 Long Integers . . . . .	542
A.2.2 Real Numbers . . . . .	543
A.2.3 Csets . . . . .	543
A.2.4 Lists . . . . .	544
A.2.5 Sets . . . . .	545

# Preface

This book is a compendium of documents that describe the implementation of the Icon and Unicon programming languages, an implementation that started with Icon version 3 on a PDP-11 sometime near the year 1980. The dynamic nature of the code pretty well guarantees that the documentation can never be complete and current.

## Organization of This Book

This book consists of four parts. The first part, Chapters 1-12, present the core of the implementation, focusing on the virtual machine interpreter and runtime system. This material was originally published as the Implementation of the Icon Programming Language, by Ralph and Madge T. Griswold; at that time it documented Icon Version 6. Many of the details in this book became obsolete with the rewriting of the runtime system for Icon Version 8. This work strives to preserve the authors' style and intent, while updating it to document Icon Version 9.5 and Unicon Version 12. Blue-colored text indicates when necessary Unicon issues and differences, so that Part I remains useful to people who prefer to use the Icon implementation, not just those working with Unicon.

Part II, in Chapters 13-19, describes the optimizing compiler, `iconc`, and the structuring of the runtime system to support it. This work is the brainchild of Ken Walker, whose dissertation is presented here, along with his technical report describing the runtime language RTL and its translator, `rtt`. Ken's compiler was enhanced by Anthony Jones' B.S. Honors thesis (Chapter 24).

Part III describes the implementation of Unicon, including chapters on the Unicon translator, the networking and POSIX system interface, the database facilities, 2D and 3D graphics, and concurrency. Part III is capped by Mike Wilder's chapters on adapting the optimizing compiler from Part II and the Unicon translator to work together, and a technique that solves the problem of memory requirements for type inferencing, enabling the optimizing compiler to handle the large number of types used in complex object-oriented programs.

Part IV consists of essential reference material presented in several Appendixes.

## Acknowledgments

This book would not be possible without the generous contributions and consent of the primary authors of the Icon language implementation documents, Ralph and Madge Griswold, and Kenneth Walker. Ralph Griswold re-scanned and corrected his Icon implementation book manuscript in order to place it in the public domain on the web, a large, selfless, thankless, and valuable undertaking. Ken Walker found and shared his original nroff dissertation source files.

Susie Jeffery provided crucial assistance in the OCR reconstruction of Icon implementation book manuscript from the public domain scanned images. Mike Kemp was a valuable volunteer proofreader in that effort. Responsibility for remaining typographical errors rests with the editor. Thanks to Don Ward and Bruce Rennie and other internet volunteers who offered implementation book corrections, which really started pouring in once its LaTeX source was added to Unicon's SVN repository.

Thanks to the rest of the people who contributed code to the Icon and Unicon Projects over a period of many years, and to those who contributed while obtaining many Ph.D. and M.S. degrees.

The editor wishes to acknowledge generous support from the National Library of Medicine. This work was also supported in part by the National Science Foundation under grants CDA-9633299, EIA-0220590 and EIA-9810732, and the Alliance for Minority Participation.

Clinton Jeffery, Moscow ID, January 2017

## Acknowledgments for Chapters 1-12

The implementation of Icon described in Part I owes much to previous work and in particular to implementations of earlier versions of Icon. Major contributions were made by Cary Coutant, Dave Hanson, Tim Korb, Bill Mitchell, a Steve Wampler. Walt Hansen, Rob McConeghy, and Janalee O'Bagy also made significant contributions to this work.

The present system has benefited greatly from persons who have installed Icon on a variety of machines and operating systems. Rick Fonorow, Bob Goldberg, Chris Janton, Mark Langley, Rob McConeghy, Bill Mitchell, Janal O'Bagy, John Polstra, Gregg Townsend, and Cheyenne Wills have made substantial contributions in this area.

The support of the National Science Foundation under Grants MCS7 01397, MCS79-03890, MCS81-01916, DCR-8320138, DCR-840183I, at DCR-8502015 was instrumental in the original conception of Icon and has been invaluable in its subsequent development.

A number of persons contributed to this book. Dave Gudeman, Dave Hanson, Bill Mitchell, Janalee O'Bagy, Gregg Townsend, and Alan Wendt contributed to the exercises that appear at the ends of chapters and the projects given in Appendix E. Kathy Cummings, Bill Griswold, Bill Mitchell, Katie Morse, Mike Tharp, and Gregg Townsend gave the manuscript careful readings and made numerous suggestions. Janalee O'Bagy not only read the manuscript but also supplied concepts for presenting and writing the material on expression evaluation.

Finally, Dave Hanson served as an enthusiastic series editor for this book. His perceptive reading of the manuscript and his supportive and constructive suggestions made a significant contribution to the final result.

*Ralph and Madge Griswold*

## **Acknowledgments for Chapters 13-24**

I would like to thank Ralph Griswold for acting as my research advisor. He provided the balance of guidance, support, and freedom needed for me to complete this research. From him I learned many of the technical writing skills I needed to compose this dissertation. I am indebted to him and the other members of the Icon Project who over the years have contributed to the Icon programming language that serves as a foundation of this research. I would like to thank Peter Downey and Saumya Debray for also serving as members on my committee and for providing insightful criticisms and suggestions for this dissertation. In addition, Saumya Debray shared with me his knowledge of abstract interpretation, giving me the tool I needed to shape the final form of the type inferencing system.

I have received help from a number of my fellow graduate students both while they were still students and from some after they graduated. Clinton Jeffery, Nick Kline, and Peter Bigot proofread this dissertation, providing helpful comments. Similarly, Janalee O’Bagy, Kelvin Nilsen, and David Gudeman proofread earlier reports that served as a basis for several of the chapters in this dissertation. Janalee O’Bagy’s own work on compiling Icon provided a foundation for the compiler I developed. Kelvin Nilsen applied my liveness analysis techniques to a slightly different implementation model, providing insight into dependencies on execution models.

## Compendium Introduction

The implementation of the Icon programming language is venerable. The implementation documentation traditionally revolved around the virtual machine and its runtime system; other parts of the implementation were documented in scattered technical reports or not at all, other than the source code. This volume changes all that, by bringing all the implementation documents together in a single volume.

Icon's public-domain implementation is fairly efficient; for example at one point Keith Walclena of the University of Chicago documented a factor of 4 or more speed advantage of Icon versus Python on multiple benchmarks, and that was for the Icon virtual machine interpreter; the Icon optimizing compiler adds another factor of 2-5 or more in faster execution speed. The design decisions that achieve Icon's very-high level language features (such as generators and goal-directed evaluation) with acceptable performance make for an interesting study. This book is intended for those wanting to learn the implementation in order to add features, improve performance, learn about compilers in general, or glean ideas for their own independent programming language efforts.

Icon traditionally consisted of a virtual machine translator, a linker, and a virtual machine interpreter. The translator and linker were merged long ago, but other tools have been added. The big added components are the optimizing compiler written by Ken Walker, and the Unicon translator written by Clint Jeffery. These additions are now a large part of the story. In the future you might hope to see merger of components, and gradual replacement of C-based components with ones written in Unicon.

## How Many Compilers?

The figure below shows two symmetrically-organized sets of tools. The tools on the left are the compilers end-users employ to translate Icon or Unicon into executable machine code, while the tools on the right show how the underlying run-time system needed in order to execute those programs is built. Of the six rectangles, four are compilers that perform distinct tasks specific to this programming language family. The front-end translation tool, named `unicon`, is a preprocessor that translates Unicon code into Icon code. Its primary functions are to translate object-orientation (classes, single and multiple inheritance, and packages) down to underlying imperative constructs. Unicon is written in Unicon. `Icont` and `iconc` compile Icon code down to virtual machine and C code, respectively. They share a few common front-end components, but are largely independent. `Iconx` is the name of the Icon (and Unicon) virtual machine, which mostly consists of a large collection of complex high-level data structure and I/O facilities which are built-in to these languages. Most of the source code for `iconx` is also used in `rt.a`, the runtime library that is linked to Icon programs compiled with `iconc`.

# **The Implementation of the Icon Programming Language**

by Ralph E. Griswold and Madge T. Griswold

# Chapter 1

## Introduction

**PERSPECTIVE:** The implementation of complex software systems is a fascinating subject — and an important one. Its theoretical and practical aspects occupy the attention and energy of many persons, and it consumes vast amounts of computational resources. In general terms, it is a broad subject ranging from operating systems to programming languages to data-base systems to real-time control systems, and so on.

Past work in these areas has resulted in an increasingly better understanding of implementation techniques, more sophisticated and efficient systems, and tools for automating various aspects of software production. Despite these advances, the implementation of complex software systems remains challenging and exciting. The problems are difficult, and every advance in the state of the art brings new and more difficult problems within reach.

Part I of this book addresses a very small portion of the problem of implementing complex software systems—the implementation of a very high-level programming language that is oriented toward the manipulation of structures and strings of characters.

In a narrow sense, this book describes an implementation of a specific programming language, Icon. In a broader sense, it deals with a language-design philosophy, an approach to implementation, and techniques that apply to the implementation of many programming languages as well as related types of software systems.

The focus of this book is the implementation of programming language features that are at a high conceptual level—features that are easy for human beings to use as opposed to features that fit comfortably on conventional computer architectures. The orientation of the implementation is generality and flexibility, rather than maximum efficiency of execution. The problem domain is strings and structures rather than numbers. It is these aspects that set the implementation of Icon apart from more conventional programming-language implementations.

## 1.1 Implementing Programming Languages

In conventional programming languages, most of the operations that are performed when a program is executed can be determined, statically, by examining the text of the program. In addition, the operations of most programming languages have a fairly close correspondence to the architectural characteristics of the computers on which they are implemented. When these conditions are met, source-code constructs can be mapped directly into machine instructions for the computer on which they are to be executed. The term *compilation* is used for this translation process, and most persons think of the implementation of a programming language in terms of a compiler.

Writing a compiler is a complex and difficult task that requires specialized training, and the subject of compilation has been studied extensively (Waite and Goos, 1984; Aho, Lam, Sethi and Ullman 2006). Most of the issues of data representation and code generation are comparatively well understood, and there are now many tools for automating portions of the compiler-writing task (Lesk 1975, Johnson 1975).

In addition to the compiler proper, an implementation of a programming language usually includes a run-time component that contains subroutines for performing computations that are too complex to compile in-line, such as input, output, and mathematical functions.

Some programming languages have features whose meanings cannot be determined statically from the text of a source-language program, but which may change during program execution. Such features include changes in the meaning of functions during execution, the creation of new data types at run time, and self-modifying programs. Some programming languages also have features, such as pattern matching, that do not have correspondences in the architecture of conventional computers. In such cases, a compiler cannot translate the source program directly into executable code. Very high-level operations, such as pattern matching, and features like automatic storage management significantly increase the importance and complexity of the run-time system. For languages with these characteristics--languages such as APL, LISP, SNOBOL4, SETL, Prolog, and Icon--much of the substance of the implementation is in the run-time system rather than in translation done by a compiler. While compiler writing is relatively well understood, run-time systems for most programming languages with dynamic features and very high-level operations are not.

Programming languages with dynamic aspects and novel features are likely to become more important rather than less important. Different problems benefit from different linguistic mechanisms. New applications place different values on speed of execution, memory requirements, quick solutions, programmer time and talent, and so forth. For these reasons, programming languages continue to proliferate. New programming languages, by their nature, introduce new features.

All of this creates difficulties for the implementer. Less of the effort involved in implementations for new languages lies in the comparatively familiar domain of compilation and more lies in new and unexplored areas, such as pattern matching and novel expression-evaluation mechanisms.

The programming languages that are the most challenging to implement are also those that

differ most from each other. Nevertheless, there are underlying principles and techniques that are generally applicable, and existing implementations contain many ideas that can be used or extended in new implementations.

## 1.2 The Background for Icon

Before describing the Icon programming language and its implementation, some historical context is needed, since both the language and its implementation are strongly influenced by earlier work.

Icon has its roots in a series of programming languages that bear the name SNOBOL. The first SNOBOL language was conceived and implemented in the early 1960s at Bell Telephone Laboratories in response to the need for a programming tool for manipulating strings of characters at a high conceptual level (Farber, Griswold, and Polonsky 1964). It emphasized ease of programming at the expense of efficiency of execution; the programmer was considered to be a more valuable resource than the computer.

This rather primitive language proved to be popular, and it was followed by successively more sophisticated languages: SNOBOL2, SNOBOL3 (Farber, Griswold, and Polonsky 1966), and finally SNOBOL4 (Griswold, Poage, and Polonsky 1971). Throughout the development of these languages, the design emphasis was on ease of programming rather than on ease of implementation (Griswold 1981). Potentially valuable features were not discarded because they might be inefficient or difficult to implement. The aggressive pursuit of this philosophy led to unusual language features and to challenging implementation problems.

SNOBOL4 still is in wide use. Considering its early origins, some of its facilities are remarkably advanced. It features a pattern-matching facility with backtracking control structures that effectively constitutes a sublanguage. SNOBOL4 also has a variety of data structures, including tables with associative lookup. Functions and operators can be defined and redefined during program execution. Identifiers can be created at run-time, and a program can even modify itself by means of run-time compilation.

Needless to say, SNOBOL4 is a difficult language to implement, and most of the conventional compilation techniques have little applicability to it. Its initial implementation was, nonetheless, sufficiently successful to make SNOBOL4 widely available on machines ranging from large mainframes to personal computers (Griswold 1972). Subsequent implementations introduced a variety of clever techniques and fast, compact implementations (Santos 1971; Gimpel 1972a; Dewar and McCann 1977). The lesson here is that the design of programming languages should not be overly inhibited by perceived implementation problems, since new implementation techniques often can be devised to solve such problems effectively and efficiently.

It is worth noting that the original implementation of SNOBOL4 was carried out concomitantly with language design. The implementation was sufficiently flexible to serve as a research tool in which experimental language features could be incorporated easily and tested before they were

given a permanent place in the language.

Work on the SNOBOL languages continued at the University of Arizona in the early 1970s. In 1975, a new language, called SL5 ("SNOBOL Language 5"), was developed to allow experimentation with a wider variety of programming-language constructs, especially a sophisticated procedure mechanism (Griswold and Hanson, 1977; Hanson and Griswold 1978). SL5 extended earlier work in pattern matching, but pattern matching remained essentially a sublanguage with its own control structures, separate from the rest of the language.

The inspiration for Icon came in 1976 with a realization that the control structures that were so useful in pattern matching could be integrated with conventional computational control structures to yield a more coherent and powerful programming language.

The first implementation of Icon (Griswold and Hanson 1979) was written in Ratfor, a pre-processor for Fortran that supports structured programming features (Kernighan 1975). Portability was a central concern in this implementation. The implementation of Icon described in this book is a successor to that first implementation. It borrows much from earlier implementations of SNOBOL4, SL5, and the Ratfor implementation of Icon. As such, it is a distillation and refinement of implementation techniques that have been developed over a period of more than twenty years.

## Chapter 2

# Icon Language Overview

**PERSPECTIVE:** The implementer of a programming language needs a considerably different understanding of the language from the persons who are going to use it. An implementer must have a deep understanding of the relationships that exist among various aspects of the language and a precise knowledge of what each operation means. Special cases and details often are of particular importance to the implementer. Users of a language, on the other hand, must know how to use features to accomplish desired results. They often can get by with a superficial knowledge of the language, and they often can use it effectively even if some aspects of the language are misunderstood. Users can ignore parts of the language that they do not need. Idiosyncrasies that plague the implementer may never be encountered by users. Conversely, a detail the implementer overlooks may bedevil users. Furthermore, the implementer may also need to anticipate ways in which users may apply some language features in inefficient and inappropriate ways.

Part I of this book is about the implementation of Version 6 (discussion partially updated to Version 9) of Icon. The description that follows concentrates on aspects of the language that are needed to understand its implementation. Where there are several similar operations or where the operations are similar to those in well-known programming languages, only representative cases or highlights are given. A complete description of Icon for the user is contained in Griswold and Griswold (1997).

Icon is an unusual programming language, and its unusual features are what make its implementation challenging and interesting. The interesting features are semantic, not syntactic; they are part of what the language can do, not part of its appearance. Syntactic matters and the way they are handled in the implementation are of little interest here. The description that follows indicates syntax mostly by example.

This chapter is divided into two major parts. The first part describes the essential aspects of Icon. The second part discusses those aspects of Icon that present the most difficult implementation problems and that affect the nature of the implementation in the most significant ways.

## 2.1 The Icon Programming Language

Icon is conventional in many respects. It is an imperative, procedural language with variables, operations, functions, and conventional data types. Its novel aspects lie in its emphasis on the manipulation of strings and structures and in its expression-evaluation mechanism. While much of the execution of an Icon program has an imperative flavor, there also are aspects of logic programming.

There are no type declarations in Icon. Instead, variables can have any type of value. Structures may be heterogeneous, with different elements having values of different types. Type checking is performed during program execution, and automatic type conversion is provided. Several operations are polymorphic, performing different operations depending on the types of their arguments.

Strings and structures are created during program execution, instead of being declared and allocated during compilation. Structures have pointer semantics; a structure value is a pointer to an object. Storage management is automatic. Memory is allocated as required, and garbage collection is performed when necessary. Except for the practical considerations of computer architecture and the amount of available memory, there are no limitations on the sizes of objects.

An Icon program consists of a series of declarations for procedures, records, and global identifiers. Icon has no block structure. Scoping is static: identifiers either are global or are local to procedures.

Icon is an expression-based language with reserved-word syntax. It resembles C in appearance, for example (Kernighan and Ritchie 1978).

### 2.1.1 Data Types

Icon has many types of data — including several that are not found in most programming languages. In addition to the usual integers and real (floating-point) numbers, there are strings of characters and sets of characters (csets). There is no character data type, and strings of characters are data objects in their own right, not arrays of characters.

There are four structure data types that comprise aggregates of values: lists, sets, tables, and records. Lists provide positional access (like vectors), but they also can be manipulated like stacks and queues. Sets are unordered collections of values on which the usual set operations can be performed. Tables can be subscripted with any kind of value and provide an associative-access mechanism. Records are aggregates of values that can be referenced by name. Record types also add to the built-in type repertoire of Icon.

The null value serves a special purpose; all variables have the null value initially. The null value is illegal in most computational contexts, but it serves to indicate default values in a number of situations. The keyword `&null` produces the null value.

A source-language file is a data value that provides an interface between the program and a data file in the environment in which the program executes.

Procedures also are data values — "first-class data objects" in LISP parlance. Procedures can be

assigned to variables, transmitted to and returned from functions, and so forth. There is no method for creating procedures during program execution, however.

Finally, there is a co-expression data type. Co-expressions are the expression-level analog of coroutines. The importance of co-expressions is derived from Icon's expression-evaluation mechanism.

Icon has various operations on different types of data. Some operations are polymorphic and accept arguments of different types. For example, `type(x)` produces a string corresponding to the type of `x`. Similarly, `copy(x)` produces a copy of `x`, regardless of its type. Other operations only apply to certain types. An example is:

```
*x
```

which produces the size of `x`, where the value of `x` may be a string, a structure, and so on. Another example is `?x`, which produces a randomly selected integer between 1 and `x`, if `x` is an integer, but a randomly selected one-character substring of `x` if `x` is a string, and so on. In other cases, different operations for similar kinds of computations are syntactically distinguished. For example,

```
i = j
```

compares the numeric values of `i` and `j`, while

```
s1 == s2
```

compares the string values of `s1` and `s2`. There is also a general comparison operation that determines whether any two objects are the same:

```
x1 === x2
```

As mentioned previously, any kind of value can be assigned to any variable. For example, `x` might have an integer value at one time and a string value at another:

```
x := 3
```

```
...
```

```
x := "hello"
```

Type checking is performed during program execution. For example, in

```
i := x + 1
```

the value of `x` is checked to be sure that it is numeric. If it is not numeric, an attempt is made to convert it to a numeric type. If the conversion cannot be performed, program execution is terminated with an error message.

Various conversions are supported. For example, a number always can be converted to a string. Thus,

```
write(*s)
```

automatically converts the integer returned by `*s` to a string for the purpose of output.

There also are explicit type-conversion functions. For example,

```
s1 := string(*s2)
```

assigns to `s1` a string corresponding to the size of `s2`.

A string can be converted to a number if it has the syntax of a number. Thus,

```
i := i + "20"
```

produces the same result as

```
i := i + 20
```

Augmented assignments are provided for binary operations such as the previous one, where assignment is made to the same variable that appears as the left argument of the operation. Therefore, the previous expression can be written more concisely as

```
i += 20
```

Icon also has the concept of a numeric type, which can be either an integer or a real (floating-point) number.

## 2.1.2 Expression Evaluation

In most programming languages — Algol, Pascal, PL/I, and C, for example — the evaluation of an expression always produces exactly one result. In Icon, the evaluation of an expression may produce a single result, it may produce no result at all, or it may produce a sequence of results.

**Success and Failure.** Conventional operations in Icon produce one result, as they do in most programming languages. For example,

```
i + j
```

produces a single result, the sum of the values of `i` and `j`. However, a comparison operation such as

```
i > j
```

produces a result (the value of `j`) if the value of `i` is greater than the value of `j` but does not produce a result if the value of `i` is not greater than `j`.

An expression that does not produce a result is said to *fail*, while an expression that produces a result is said to *succeed*. Success and failure are used in several control structures to control program flow. For example,

```
if i > j then write(i) else write(j)
```

writes the maximum of `i` and `j`. Note that comparison operations do not produce Boolean values and that Boolean values are not used to drive control structures. Indeed, Icon has no Boolean type.

Generally speaking, an operation that cannot perform a computation does not produce a result, and hence it fails. For example, type-conversion functions fail if the conversion cannot be performed. An example is `numeric(x)`, which converts `x` to a numeric value if possible, but fails if the conversion cannot be performed. Failure of an expression to produce a result does not indicate an error. Instead, failure indicates that a result does not exist. An example is provided by the function `find(s1, s2)`, which produces the position of `s1` as a substring of `s2` but fails if `s1` does not occur in `s2`. For example,

```
find("it", "They sit like bumps on a log.")
```

produces the value 7 (positions in strings are counted starting at 1). However,

```
find("at", "They sit like bumps on a log.")
```

does not produce a result. Similarly, `read(f)` produces the next line from the file `f` but fails when the end of the file is reached.

Failure provides a natural way to control loops. For example,

```
while line := read(f) do
  write(line)
```

writes the lines from the file `f` until an end of file causes `read` to fail, which terminates the loop.

Another use of success and failure is illustrated by the operation

```
\expr
```

which fails if *expr* is null-valued but produces the result of *expr* otherwise. Since variables have the null value initially, this operation may be used to determine whether a value has been assigned to an identifier, as in

```
if \x then write(x) else write("x is null")
```

If an expression that is enclosed in another expression does not produce a result, there is no value for the enclosing expression, it cannot perform a computation, and it also produces no result. For example. In

```
write(find("at", "They sit like bumps on a log.))
```

the evaluation of `find` fails, there is no argument for `write`, and no value is written.

Similarly, in

```
i := find("at", "They sit like bumps on a log.")
```

the assignment is not performed and the value of `i` is not changed.

This “inheritance” of failure allows computations to be expressed concisely. For example,

```
while write(read(f))
```

writes the lines from the file `f` just as the previous loop (the `do` clause in `while-do` is optional).

The expression

```
not expr
```

inverts success and failure. It fails if *expr* succeeds, but it succeeds, producing the null value, if *expr* fails.

Some expressions produce variables, while others only produce values. For example,

```
i + j
```

produces a value, while

```
i := 10
```

produces its left-argument variable. The term *result* is used to refer to a value or a variable. The term *outcome* is used to refer to the consequences of evaluating an expression — either its result or failure.

**Loops.** There are several looping control structures in Icon in addition to while-do. For example,

```
until expr1 do expr2
```

evaluates *expr2* repeatedly until *expr1* succeeds. The control structure

```
repeat expr
```

simply evaluates *expr* repeatedly, regardless of whether it succeeds or fails.

A loop itself produces no result if it completes, and hence it fails if used in a conditional context. That is, when

```
while expr1 do expr2
```

terminates, its outcome is failure. This failure ordinarily goes unnoticed, since loops usually are not used as arguments of other expressions.

The control structure

```
break expr
```

causes the immediate termination of the evaluation of the loop in which it appears, and control is transferred to the point immediately after the loop. The outcome of the loop in this case is the outcome of *expr*. If *expr* is omitted, it defaults to the null value.

An example of the use of break is:

```
while line := read(f) do
  if line == "end" then break
  else write(line)
```

Evaluation of the loop terminates if read fails or if the file *f* contains a line consisting of “end”. The expression next causes transfer to the beginning of the loop in which it occurs. For example,

```
while line := read(f) do
  if line == "comment" then next
  else write(line)
```

does not write the lines of *f* that consist of “comment”.

The break and next expressions can occur only in loops, and they apply to the innermost loop in which they appear. The argument of break can be a break or next expression, however, so that, for example,

```
break break next
```

breaks out of two levels of loops and transfers control to the beginning of the loop in which they occur.

**Case Expressions.** The case expression provides a way of selecting one of several expressions to evaluate based on the value of a control expression, rather than its success or failure. The case expression has the form

```

case expr of {
  case clauses
  ...
}

```

The value of *expr* is used to select one of the case clauses. A case clause has the form

*expr1* : *expr2*

where the value of *expr* is compared to the value of *expr1*, and *expr2* is evaluated if the comparison succeeds. There is also a default case clause, which has the form

default: *expr3*

If no other case clause is selected, *expr3* in the default clause is evaluated. An example is

```

case line := read(f) of {
  "end":  write("*** end ***")
  "comment": write("*** comment ***")
  default: write(line)
}

```

If the evaluation of the control clause fails, as for an end of file in this example, the entire case expression fails. Otherwise, the outcome of the case expression is the outcome of evaluating the selected expression.

**Generators.** As mentioned previously, an expression may produce a sequence of results. This occurs in situations in which there is more than one possible result of a computation. An example is

```
find("e", "They sit like bumps on a log.")
```

in which both 3 and 13 are possible results.

While most programming languages produce only the first result in such a situation, in Icon the two results are produced one after another if the surrounding context requires both of them. Such expressions are called *generators* to emphasize their capability of producing more than one result.

There are two contexts in which a generator can produce more than one result: *iteration* and *goal-directed evaluation*.

Iteration is designated by the control structure

every *expr1* do *expr2*

in which *expr1* is repeatedly resumed to produce its results. For each such result, *expr2* is evaluated. For example,

```

every i := find("e", "They sit like bumps on a log.")
do
  write(i)

```

writes 3 and 13.

If the argument of an expression is a generator, the results produced by the generator are provided to the enclosing expression—the sequence of results is inherited. Consequently, the previous expression can be written more compactly as

```

every write(find("e", "They sit like bumps on a log.))

```

Unlike iteration, which resumes a generator repeatedly to produce all its results, goal-directed evaluation resumes a generator only as necessary, in an attempt to cause an enclosing expression to succeed. While iteration is explicit and occurs only where specified, goal-directed evaluation is implicit and is an inherent aspect of Icon's expression-evaluation mechanism.

Goal-directed evaluation is illustrated by

```

if find("e", "They sit like bumps on a log") > 10
then write("found")

```

The first result produced by `find()` is 3, and the comparison operation fails. Because of goal-directed evaluation, `find` is automatically resumed to produce another value. Since this value, 13, is greater than 10, the comparison succeeds, and `found` is written. On the other hand, in

```

if find("e", "They sit like bumps on a log.") > 20
then write("found")

```

the comparison fails for 3 and 13. When `find` is resumed again, it does not produce another result, the control clause of `if-then` fails, and nothing is written.

There are several expressions in Icon that are generators, including string analysis functions that are similar in nature to `find`. Another generator is

```

i to j by k

```

which generates the integers from `i` to `j` by increments of `k`. If the `by` clause is omitted, the increment defaults to one.

The operation `!x` is polymorphic, generating the elements of `x` for various types. The meaning of "element" depends on the type of `x`. If `x` is a string, `!x` generates the one-character substrings of `x`, so that `! "hello"` generates `"h"`, `"e"`, `"l"`, `"l"`, and `"o"`. If `x` is a file, `!x` generates the lines of the file, and so on.

**Generative Control Structures.** There are several control structures related to generators. The *alternation* control structure,

```

expr1 | expr2

```

generates the results of *expr1* followed by the results of *expr2*. For example,

*every write("hello" | "howdy")*

writes two lines, hello and howdy.

Since alternation succeeds if either of its arguments succeeds, it can be used to produce the effect of logical disjunction. An example is

*if (i > j) | (j > k) then expr*

which evaluates *expr* if *i* is greater than *j* or if *j* is greater than *k*.

Logical conjunction follows as a natural consequence of goal-directed evaluation. The operation

*expr1 & expr2*

is similar to other binary operations, such as *expr1 + expr2*, except that it performs no computation.

Instead, it produces the result of *expr2*, provided that both *expr1* and *expr2* succeed. For example,

*if (i > j) & (j > k) then expr*

evaluates *expr* only if *i* is greater than *j* and *j* is greater than *k*.

Repeated alternation,

*|expr*

generates the results of *expr* repeatedly and is roughly equivalent to

*expr | expr | expr | ...*

However, if *expr* fails, the repeated alternation control structure stops generating results. For example,

*|read(f)*

generates the lines from the file *f* (one line for each repetition of the alternation) but stops when *read(f)* fails.

Note that a generator may be capable of producing an infinite number of results. For example,

*| (1 to 3)*

can produce 1, 2, 3, 1, 2, 3, 1, 2, 3. However, only as many results as are required by context are actually produced. Thus,

*i := | (1 to 3)*

only assigns the value 1 to *i*, since there is no context to cause the repeated alternation control structure to be resumed for a second result.

The *limitation* control structure

*expr1 \ expr2*

limits *expr1* to at most *expr2* results. Consequently,

*| (1 to 3) \ 5*

is only capable of producing 1, 2, 3, 1, 2.

**The Order of Evaluation.** With the exception of the limitation control structure, argument evaluation in Icon is strictly left-to-right. The resumption of expressions to produce additional results is in last-in, first-out order. The result is "cross-product" generation of results in expressions that contain several generators. For example,

*every write((10 to 30 by 10) + (1 to 3))*

writes 11, 12, 13, 21, 22, 23, 31, 32, 33.

**Control Backtracking.** Goal-directed evaluation results in control backtracking to obtain additional results from expressions that have previously produced results, as in

```
if find("e", "They sit like bumps on a log.") > 10
then write("found")
```

Control backtracking is limited by a number of syntactic constructions. For example, in

```
if expr1 then expr2 else expr3
```

if *expr1* succeeds, but *expr2* fails, *expr1* is not resumed for another result. (If it were, the semantics of this control structure would not correspond to what "if-then-else" suggests.) Such an expression is called a *bounded expression*. The control clauses of loops also are bounded, as are the expressions within compound expressions:

```
{ expr1 ; expr2 ; expr3 ; ... ; exprn }
```

These expressions are evaluated in sequence, but once the evaluation of one is complete (whether it succeeds or fails), and the evaluation of another begins, there is no possibility of backtracking into the preceding one. The last expression in a compound expression is not bounded, however.

Except in such specific situations, expressions are not bounded. For example, in

```
if expr1 then expr2 else expr3
```

neither *expr2* nor *expr3* is bounded. Since Icon control structures are expressions that may return results, it is possible to write expressions such as

```
every write(if i > j then j to i else i to j)
```

which writes the integers from i to j in ascending sequence.

**Data Backtracking.** While control backtracking is a fundamental part of expression evaluation in Icon, data backtracking is not performed except in a few specific operations. For example, in

```
(i := 3) & read(f)
```

the value 3 is assigned to i. Even if read(f) fails, the former value of i is not restored.

There are, however, specific operations in which data backtracking is performed. For example, the *reversible assignment* operation

```
x <- y
```

assigns the value of y to x, but it restores the former value of x if control backtracking into this expression occurs. Thus,

```
(i <- 3) & read(f)
```

assigns 3 to i but restores the previous value of i if read(f) fails.

### 2.1.3 Csets and Strings

Csets are unordered sets of characters, while strings are sequences of characters. There are 256 different characters, the first 128 of which are interpreted as ASCII. The number and interpretation of characters is independent of the architecture of the computer on which Icon is implemented.

**Csets.** Csets are represented literally by surrounding their characters by single quotation marks. For example,

```
vowels := 'aeiouAEIOU'
```

assigns a cset of 10 characters to vowels.

There are several built-in csets that are the values of keywords. These include `&lcase`, `&ucase`, and `&cset`, which contain the lowercase letters, the uppercase letters, and all 256 characters, respectively.

Operations on csets include union, intersection, difference, and complement with respect to `&cset`. Csets are used in lexical analysis. For example, the function `upto(c, s)` is analogous to `find(s1, s2)`, except that it generates the positions at which any character of `c` occurs in `s`. Thus,

```
upto(vowels, "They sit like bumps on a log.")
```

is capable of producing 3, 7, 11, 13, 16, 21, 24, and 27.

**Strings.** Strings are represented literally by surrounding their characters with double quotation marks instead of single quotation marks. The empty string, which contains no characters, is given by `""`. The size of a string is given by `*s`. For example, if

```
command := "Sit still!"
```

then the value of `*command` is 10. The value of `""` is 0. Space for strings is provided automatically and there is no inherent limit to the size of a string.

There are several operations that construct strings. The principal one is concatenation, denoted by

```
s1 || s2
```

The function `repl(s, i)` produces the result of concatenating `s` `i` times. Thus,

```
write(repl("!",3))
```

writes `*!*!*`.

Other string construction functions include `reverse(s)`, which produces a string with the characters of `s` in reverse order, and `trim(s, c)`, which produces a string in which trailing characters of `s` that occur in `c` are omitted. There also are functions for positioning a string in a field of a fixed width. For example, the function `left(s1,i, s2)` produces a string of length `i` with `s1` positioned at the left and padded with copies of `s2` as needed.

Substrings are produced by subscripting a string with the beginning and ending positions of the desired substring. Positions in strings are between characters, and the position before the first character of a string is numbered 1. For example,

```
verb := command[1:4]
```

assigns the string "Sit" to verb. Substrings also can be specified by the beginning position and a length, as in

```
verb := command[1+:3]
```

If the length of a substring is 1, only the first position need be given, so that the value of `command[2]` is "i".

Assignment can be made to a subscripted string to produce a new string. For example,

```
command[1:4] := "Remain"
```

changes the value of `command` to "Remain still!".

String operations are applicative; no operation on a string in Icon changes the characters in it. The preceding example may appear to contradict this, but in fact

```
command[1:4] := "Remain"
```

is an abbreviation for

```
command := "Remain" || command[5:11]
```

Thus, a new string is constructed and then assigned to `command`.

Nonpositive values can be used to specify a position with respect to the right end of a string. For example, the value of `command[-1]` is "!". The value 0 refers to the position after the last character of a string, so that if the value of `command` is "Sit still!",

```
command[5:0]
```

is equivalent to

```
command[5:11]
```

The subscript positions can be given in either order. Thus,

```
command[11:5]
```

produces the same result as

```
command[5:11]
```

String-analysis functions like `find` and `upto` have optional third and fourth arguments that allow their range to be restricted to a particular portion of a string. For example,

```
upto(vowels, "They sit like bumps on a log.", 10, 20)
```

only produces positions of vowels between positions 10 and 20 of its second argument: 11, 13, and 16. If these arguments are omitted, they default to 1 and 0, so that the entire string is included in the analysis.

**Mapping.** One of the more interesting string-valued functions in Icon is `map(s1, s2, s3)`. This function produces a string obtained from a character substitution on `s1`. Each character of `s1` that occurs in `s2` is replaced by the corresponding character in `s3`. For example,

```
write(map("Remain still!", "aeiou", "*****"))
```

writes `R*m**n St*ll!`. Characters in `s1` that do not appear in `s2` are unchanged, as this example shows. If a character occurs more than once in `s2`, its right-most correspondence in `s3` applies. Consequently,

```

s2 := &lcase || &ucase || "aeiou"
s3 := repl("|",26) ||
repl("u",26) || "*****"
write(map("Remain still!", s2, s3))

```

writes `u*|**| ||*||!` .

### 2.1.4 String Scanning

String scanning is a high-level facility for string analysis that suppresses the computational details associated with the explicit location of positions and substring specifications. In string scanning, a subject serves as a focus of attention. A position in this subject is maintained automatically.

A string-scanning expression has the form

*expr1 ? expr2*

in which the evaluation of *expr1* provides the subject. The position in the subject is 1 initially. The expression *expr2* is then evaluated in the context of this subject and position.

Although *expr2* can contain any operation, two *matching functions* are useful in analyzing the subject:

`tab(i)`            set the position in the subject to *i*

`move(i)`          increment the position in the subject by *i*

Both of these functions return the substring of the subject between the old and new positions. If the position is out of the range of the subject, the matching function fails and the position is not changed. The position can be increased or decreased. Nonpositive values can be used to refer to positions relative to the end of the subject. Thus, `tab(0)` moves the position to the end of the subject, matching the remainder of the subject.

An example of string scanning is

`line ? while write(move(2))`

which writes successive two-character substrings of `line`, stopping when there are not two characters remaining.

In string scanning, the trailing arguments of string analysis functions such as `find` and `upto` are omitted; the functions apply to the subject at the current position. Therefore, such functions can be used to provide arguments for matching functions. An example is

`line ? write(tab(find("::=")))`

which writes the initial portion of `line` up to an occurrence of the string `"::="`.

If a matching function is resumed, it restores the position in the subject to the value that it had before the matching function was evaluated. For example, suppose that `line` contains the substring `"::="`. Then

```
line ? ((tab(find("::=") + 3)) & write(move(10)) | write(tab(0)))
```

writes the 10 characters after "::=", provided there are 10 more characters. However, if there are not 10 characters remaining, `move(10)` fails and `tab(find("::="))` is resumed. It restores the position to the beginning of the subject, and the alternative, `tab(0)`, matches the entire subject, which is written.

Data backtracking of the position in the subject is important, since it allows matches to be performed with the assurance that any previous alternatives that failed to match left the position where it was before they were evaluated.

The subject and position are directly accessible as the values of the keywords `&subject` and `&pos`, respectively. For example,

```
&subject := "Hello"
```

assigns the string "Hello" to the subject. Whenever a value is assigned to the subject, `&pos` is set to 1 automatically.

The values of `&subject` and `&pos` are saved at the beginning of a string-scanning expression and are restored when it completes. Consequently, scanning expressions can be nested.

### 2.1.5 Lists

A list is a linear aggregate of values ("elements"). For example,

```
cities := ["Portland", "Toledo", "Tampa"]
```

assigns a list of three strings to `cities`. Lists can be heterogeneous, as in

```
language := ["Icon", 1978, "The University of Arizona"]
```

An empty list, containing no elements, is produced by `[ ]`. The function

```
list(i, x)
```

produces a list of `i` elements, each of which has the value of `x`. The size operation `*x` also applies to lists. The value of `*cities` is 3, for example.

An element of a list is referenced by a subscripting expression that has the same form as the one for strings. For example,

```
cities[3] := "Miami"
```

changes the value of `cities` to

```
["Portland", "Toledo", "Miami"]
```

The function `sort(a)` produces a sorted copy of `a`. For example, `sort(cities)` produces

```
["Miami", "Portland", "Toledo"]
```

List operations, unlike string operations, are not applicative. While assignment to a substring is an abbreviation for concatenation, assignment to a subscripted list changes the value of the subscripted element.

A list value is a pointer to a structure that contains the elements of the list. Assignment of a list value copies this pointer, but it does not copy the structure. Consequently, in

```
states := ["Nevada", "Texas", "Maine", "Georgia"]
slist := states
```

both `states` and `slist` point to the *same* structure. Because of this,

```
states[2] := "Arkansas"
```

changes the second element of `slist` as well as the second element of `states`.

The elements of a list may be of any type, including lists, as in

```
tree := ["a", ["b", ["c"], ["d"]]]
```

which can be depicted as

Structures also can be used to represent loops, as in

```
graph := ["a", ""]
graph[2] := graph
```

which can be depicted as

Lists are not fixed in size. Elements can be added to them or removed from them at their ends by queue and stack functions.

The function `put(a, x)` adds the value of `x` to the right end of the increasing its size by one. Similarly, `push(a, x)` adds the value of `x` to the left end of `a`. For example,

```
lines := []
while put(lines, read(f))
```

constructs a list of the lines from the file `f`. Conversely,

```
lines := []
while push(lines, read(f))
```

constructs a list of lines in reverse order.

The functions `pop(a)` and `get(a)` are the same. They both remove an element from the left end of `a` and return it as the value of the function call, but they fail if `a` is empty. Consequently,

```

lines := []
while push(lines, read(f))
while write(pop(lines))

```

writes out the lines of *f* in reverse order. The function `pull(a)` is similar, but it removes an element from the right end of *a*.

Other operations on lists include concatenation, which is denoted by

```
a1 ||| a2
```

where *a1* and *a2* are lists. There is no automatic conversion of other types to lists.

List sectioning is denoted by

```
a[i:j]
```

The result is a *new* list containing values *i* through *j* of *a*.

There is no inherent limit to the size of a list, either when it is originally created or as a result of adding elements to it.

## 2.1.6 Sets

A set is an unordered collection of values. Unlike *csets*, which contain only characters, sets are collections of Icon values that can be of any type. A set is constructed from a list by `set(a)`. For example,

```
states := set(["Virginia", "Rhode Island", "Kansas", "Illinois"])
```

assigns a set of four elements to *states*.

The operation

```
member(s, x)
```

succeeds if the value of *x* is a member of *s* but fails otherwise. The operation

```
insert(s, x)
```

adds the value of *x* to *s* if it is not already a member of *s*, while

```
delete(s, x)
```

deletes the value of *x* from *s*. The operations of union, intersection, and difference for sets also are provided.

Like other structures, sets can be heterogeneous. A set can even be a member of itself, as in

```
insert(s, s)
```

There is no contradiction here, since a set value is a pointer to the structure for the set.

### 2.1.7 Tables

A table is a set of pairs of values. Tables provide an associative look mechanism as contrasted with positional references to lists. They can be subscripted with an *entry value* to which a value can be assigned to make up a pair called a table element.

A table is created by

```
table(x)
```

Tables are empty initially. The value of *x* is an assigned default value that is produced if the table is subscripted with an entry value to which no value has been assigned (that is, for an element that is not in the table). For example,

```
states := table(0)
```

assigns to *states* a table with a default value of 0. An element can be added to *states* by an assignment such as

```
states["Oregon"] := 1
```

which adds a table element for "Oregon" with the value 1 to *states*. On the other hand,

```
write(states ["Utah"])
```

writes 0, the default value, if there is no element in the table for "Utah".

Tables can be heterogeneous and have a mixture of types for entry and assigned values. Tables grow automatically in size as new elements are added and there is no inherent limit on the size of a table.

### 2.1.8 Records

A record is an aggregate of values that is referenced by named fields. Each record type has a separate name. A record type and the names of its fields are given in a declaration. For example,

```
record rational(numerator, denominator)
```

declares a record of type *rational* with two fields: *numerator* and *denominator*.

An instance of a record is created by calling a record-constructor function corresponding to the form of the declaration for the record type. Thus,

```
r := rational(3,5)
```

assigns to *r* a record of type *rational* with a *numerator* field of 3 and a *denominator* field of 5. Fields are referenced by name, as in

```
write(r.numerator)
```

which writes 3. Fields can also be referred to by position; *r[1]* is equivalent to *r.numerator*.

There is no inherent limit to the number of different record types. The same field names can be given for different record types, and such fields need not be in the same position for all such record types.

### 2.1.9 Input and Output

Input and output in Icon are sequential and comparatively simple. The standard input, standard output, and standard error output files are the values of `&input`, `&output`, and `&errout`, respectively.

The function

```
open(s1,s2)
```

opens the file whose name is `s1` according to options given by `s2` and produces a value of type `file`. Typical options are `"r"` for opening for reading and `"w"` for opening for writing. The default is `"r"`. For example,

```
log := open("grade.log", "w")
```

assigns a value of type `file` to `log`, corresponding to the data file `grade.log`, which is opened for writing. The function `open` fails if the specified file cannot be opened according to the options given. The function `close(f)` closes the file `f`.

The function `read(f)` reads a line from the file `f` but fails if an end of file is encountered. The default is standard input if `f` is omitted.

The result of

```
write(x1,x2, ..., xn)
```

depends on the types of `x1`, `x2`, ..., `xn`. Strings and types convertible to strings are written, but if one of the arguments is a file, subsequent strings are written to that file. The default file is standard output. Thus,

```
write(s1,s2)
```

writes the concatenation of `s1` and `s2` to standard output, but

```
write(log,s)
```

writes `s` to the file `grade.log`. In any event, `write` returns the string value of the last argument written.

The function

```
stop(x1, x2, ..., xn)
```

produces the same output as `write`, but it then terminates program execution.

### 2.1.10 Procedures

**Procedure Declarations.** The executable portions of an Icon program are contained in procedure declarations. Program execution begins with a call of the procedure `main`.

An example of a procedure declaration is:

```

procedure maxstr(slist)
  local max, value
  max := 0
  every value := *!slist do
    if value > max then max := value
  return max
end

```

This procedure computes the longest string in a list of strings. The formal parameter `slist` and the identifiers `max` and `value` are local to calls of the procedure `maxstr()`. Storage for them is allocated when `maxstr()` is called and deallocated when `maxstr()` returns.

A procedure call has the same form as a function call. For example,

```

lines := []
while put(lines, read(f))
  write(maxstr(lines))

```

writes the length of the longest line in the file `f`.

A procedure call may fail to produce a result in the same way that a built-in operation can fail. This is indicated by `fail` in the procedure body in place of `return`. For example, the following procedure returns the length of the longest string in `slist` but fails if that length is less than `limit`:

```

procedure maxstr(slist, limit)
  local max, value
  max := 0
  every value := *!slist do
    if value > max then max := value
  if max < limit then fail else return max
end

```

Flowing off the end of a procedure body without an explicit `return` is equivalent to `fail`.

A procedure declaration may have static identifiers that are known only to calls of that procedure but whose values are not destroyed when a call returns. A procedure declaration also may have an initial clause whose expression is evaluated only the first time the procedure is called. The use of a static identifier and an initial clause is illustrated by the following procedure, which returns the longest of all the strings in the lists it has processed:

```

procedure maxstrall(slist)
  local value
  static max
  initial max := 0
  every value := *!slist do
    if value > max then max := value
  return max
end

```

**Procedures and Functions.** Procedures and functions are used in the same way. Their names have global scope. Other identifiers can be declared to have global scope, as in

```
global count
```

Such global declarations are on a par with procedure declarations and cannot occur within procedure declarations.

A call such as

```
write(maxstr(lines))
```

applies the *value* of the identifier *maxstr* to *lines* and applies the *value* of the identifier *write* to the result. There is nothing fixed about the values of such identifiers. In this case, the initial value of *maxstr* is a procedure, as a consequence of the procedure declaration for it. Similarly, the initial value of *write* is a function. These values can be assigned to other variables, as in

```

print := write
      :
print(maxstr(lines))

```

in which the function that is the initial value of *write* is assigned to *print*.

Similarly, nothing prevents an assignment to an identifier whose initial value is a procedure. Consequently,

```
write := 3
```

assigns an integer to *write*, replacing its initial function value.

Although it is typical to call a procedure by using an identifier that has the procedure value, the procedure used in a call can be computed. The general form of a call is

$$expr_0(expr_1, expr_2, \dots, expr_n)$$

where the value of  $expr_0$  is applied to the arguments resulting from the evaluation of  $expr_1$   $expr_2$ , ...,  $expr_n$ . For example,

$$(\text{proclist}[i])(expr_1, expr_2, \dots, expr_n)$$

applies the procedure that is the *i*th element of *proclist*.

Procedures may be called recursively. The recursive nature of a call depends on the fact that procedure names are global. The “Fibonacci strings” provide an example:

```

procedure fibstr(i)
  if i = 1 then return "a"
  else if i = 2 then return "b"
  else return fibstr(i - 1) || fibstr(i - 2)
end

```

An identifier that is not declared in a procedure and is not global defaults to local. Thus, local declarations can be omitted, as in

```

procedure maxstr(slist)
  max := 0
  every value := * !slist do
    if value > max then max := value
  return max
end

```

**Procedures as Generators.** In addition to returning and failing, a procedure can also suspend. In this case, the values of its arguments and local identifiers are not destroyed, and the call can be resumed to produce another result in the same way a built-in generator can be resumed. An example of such a generator is

```

procedure intseq(i)
  repeat {
    suspend i
    i += 1
  }
end

```

A call `intseq(10)`, for example, is capable of generating the infinite sequence of integers 10, 11, 12, .... For example,

```
every f(intseq(10) \ 5)
```

calls `f(10)`, `f(11)`, `f(12)`, `f(13)`, `f(14)`.

If the argument of `suspend` is a generator, the generator is resumed when the call is resumed and the call suspends again with the result it produces. A generator of the Fibonacci strings provides an example:

```

procedure fibstrseq()
  local s1, s2, s3
  s1 := "a"
  s2 := "b"
  suspend (s1 | s2)
  repeat {
    suspend s3 := s1 || s2
    s1 := s2
    s2 := s3
  }
end

```

When this procedure is called, the first suspend expression produces the value of `s1`, "a". If the call of `fibstrseq()` is resumed, the argument of `suspend` is resumed and produces the value of `s2`, "b". If the call is resumed again, there is no further result for the first suspend, and evaluation continues to the repeat loop.

Repeated alternation often is useful in supplying an endless number of alternatives. For example, the procedure `intseq(i)` can be rewritten as

```

procedure intseq(i)
  suspend i | (i += |1)
end

```

Note that `|1` is used to provide an endless sequence of increments.

**Argument Transmission.** Omitted arguments in a procedure or function call (including trailing ones) default to the null value. Extra arguments are evaluated, but their values are discarded.

Some functions, such as `write()`, may be called with an arbitrary number of arguments. All arguments to procedures and functions are passed by value. If the evaluation of an argument expression fails, the procedure or function is not called. This applies to extra arguments. Arguments are not dereferenced until all of them have been evaluated. Dereferencing cannot fail. Since no argument is dereferenced until all argument expressions are evaluated, expressions with side effects can produce unexpected results. Thus, in

```
write(s, s := "hello")
```

the value written is `hellohello`, regardless of the value of `s` before the evaluation of the second argument of `write()`.

**Dereferencing in Return Expressions.** The result returned from a procedure call is dereferenced unless it is a global identifier, a static identifier, a subscripted structure, or a subscripted string-valued global identifier.

In these exceptional cases, the variable is returned and assignment can be made to the procedure call. An example is

```

procedure maxel(a, i, j)
  if i > j then return a[i]
  else return a[j]
end

```

Here a list element, depending on the values of  $i$  and  $j$ , is returned. An assignment can be made to it, as in

```
maxel(lines, i, j) := "end"
```

which assigns "end" to  $\text{lines}[i]$  or  $\text{lines}[j]$ , depending on the values of  $i$  and  $j$ .

**Mutual Evaluation.** In a call expression, the value of  $\text{expr}_0$  can be an integer  $i$  as well as a procedure. In this case, called *mutual evaluation*, the result of the  $i$ th argument is produced. For example,

```
i := 1(find(s1, line1), find(s2, line2))
```

assigns to  $i$  the position of  $s1$  in  $\text{line1}$ , provided  $s1$  occurs in  $\text{line1}$  and that  $s2$  occurs in  $\text{line2}$ . If either call of  $\text{find}$  fails, the expression fails and no assignment is made.

The selection integer in mutual evaluation can be negative, in which case it is interpreted relative to the end of the argument list. Consequently,

```
(-1)( $\text{expr}_1, \text{expr}_2, \dots, \text{expr}_n$ )
```

produces the result of  $\text{expr}_n$  and is equivalent to

```
 $\text{expr}_1 \& \text{expr}_2 \& \dots \& \text{expr}_n$ 
```

The selection integer can be omitted, in which case it defaults to -1.

### 2.1.11 Co-Expressions

The evaluation of an expression in Icon is limited to the site in the program where it appears. Its results can be produced only at that site as a result of iteration or goal-directed evaluation. For example, the results generated by  $\text{intseq}(i)$  described in Section 2.1.10 can only be produced where it is called, as in

```
every f(intseq(10) \ 5)
```

It is often useful, however, to be able to produce the results of a generator at various places in the program as the need for them arises. Co-expressions provide this facility by giving a context for the evaluation of an expression that is maintained in a data structure. Co-expressions can be *activated* to produce the results of a generator on demand, at any time and place in the program.

A co-expression is constructed by

```
create  $\text{expr}$ 
```

The expression  $\text{expr}$  is not evaluated at this time. Instead, an object is produced through which  $\text{expr}$  can be resumed at a later time. For example,

```
label := create ("L" || (1 to 100) || ":")
```

assigns to  $\text{label}$  a co-expression for the expression

```
"L" || (1 to 100) || ":"
```

The operation  $\text{@label}$  activates this co-expression, which corresponds to resuming its expression. For example,

```

write(@label)
write("  tstl  count")
write(@label)

```

writes

```

L1:
    tstl  count
L2:

```

If the resumption of the expression in a co-expression does not produce a result, the co-expression activation fails. For example, after @label has been evaluated 100 times, subsequent evaluations of @label fail. The number of results that a co-expression *e* has produced is given by \**e*.

The general form of the activation expression is

*expr1 @ expr2*

which activates *expr2* and transmits the result of *expr1* to it. This form of activation can be used to return a result to the co-expression that activated the current one.

A co-expression is a value like any other value in Icon and can be passed as an argument to a procedure, returned from a procedure. and so forth. A co-expression can survive the call of the procedure in which it is created.

If the argument of a create expression contains identifiers that are local to the procedure in which the create occurs, copies of these local identifiers are included in the co-expression with the values they have at the time the create expression is evaluated. These copied identifiers subsequently are independent of the local identifiers in the procedure. Consider, for example,

```

procedure labgen(tag)
  local i, j
  ...
  i := 10
  j := 20
  e := create (tag || (i to j) || ":")
  ...
  i := j
  if i > 15 then return e
  ...
end

```

The expression

```
labels := labgen("X")
```

assigns to labels a co-expression that is equivalent to evaluating

```
create ("X" || (10 to 20) || ":")
```

The fact that *i* is changed after the co-expression was assigned to *e*, but before *e* returns, does not affect the co-expression, since it contains copies of *i* and *j* at the time it was created. Subsequent changes to the values of *i* or *j* do not affect the co-expression.

A copy of a co-expression *e* is produced by the *refresh* operation,  $\hat{e}$ . When a refreshed copy of a co-expression is made, its expression is reset to its initial state, and the values of any local identifiers in it are reset to the values they had when the co-expression was created. For example,

```
newlabels := ^labels
```

assigns to *newlabels* a co-expression that is capable of producing the same results as *labels*, regardless of whether or not *labels* has been activated.

The value of the keyword *&main* is the co-expression for the call of *main()* that initiates program execution.

## 2.1.12 Diagnostic Facilities

**String Images.** The function *type(x)* only produces the string name of the type of *x*, but the function *image(x)* produces a string that shows the value of *x*. For strings and csets, the value is shown with surrounding quotation marks in the fashion of program literals. For example,

```
write(image("Hi there!"))
```

writes "Hi there!", while

```
write(image('aeiou'))
```

writes 'aeiou'.

For structures, the type name and size are given. For example,

```
write(image([]))
```

writes *list(0)*.

Various forms are used for other types of data, using type names where necessary so that different types of values are distinguishable.

**Tracing.** If the value of the keyword *&trace* is nonzero, a trace message is produced whenever a procedure is called, returns, fails, suspends, or is resumed. Trace messages are written to standard error output. The value of *&trace* is decremented for every trace message. Tracing stops if the value of *&trace* becomes zero, which is its initial value. Suppose that the following program is contained in the file *fibstr.icn*:

```

procedure main()
  &trace := -1
  fibstr(3)
end

procedure fibstr(i)
  if i = 1 then return "a"
  else if i = 2 then return "b"
  else return fibstr(i - 1) || fibstr(i - 2)
end

```

The trace output of this program is

```

fibstr.icn: 3      | fibstr(3)
fibstr.icn: 9      | | fibstr(2)
fibstr.icn: 8      | | fibstr returned "b"
fibstr.icn: 9      | | fibstr(1)
fibstr.icn: 7      | | fibstr returned "b"
fibstr.icn: 9      | | fibstr returned "ba"
fibstr.icn: 4      | main failed

```

In addition to the indentation corresponding to the level of procedure call, the value of the keyword `&level` also is the current level of call.

**Displaying Identifier Values.** The function `display(i,f)` writes a list of all identifiers and their values for `i` levels of procedure calls, starting at the current level. If `i` is omitted, the default is `&level`, while if `f` is omitted, the list is written to standard error output. The format of the listing produced by `display` is illustrated by the following program:

```

procedure main()
  log := open("grade.log", "w")
  while write(log, check(readO))
end

```

```

procedure check(value)
  static count
  initial count := 0
  if numeric(value) then {
    count += 1
  }
end

```

```

        return value
    }
else {
    display()
    stop("nonnumeric value")
}
end

```

Suppose that the tenth line of input is the nonnumeric string "3.a". Then the output of display() is

```

check local identifiers:
  value = "3.a"
  count = 9
main local identifiers:
  log = file(grade.log)
global identifiers:
  main = procedure main
  check = procedure check
  open = function open
  write = function write
  read = function read
  numeric = function numeric
  display = function display
  stop = function stop

```

**Error Messages.** If an error is encountered during program execution, a message is written to standard error output and execution is terminated. For example, if the tenth line of a program contained in the file check.icn is

```
i +:= "x"
```

evaluation of this expression produces the error message

```

Run-time error 102 at line 10 in check.icn
numeric expected
offending value: "x"

```

## 2.2 Language Features and the Implementation

Even a cursory consideration of Icon reveals that some of its features present implementation problems and require approaches that are different from ones used in more conventional languages. In the case of a language of the size and complexity of Icon, it is important to place different aspects of the implementation in perspective and to identify specific problems.

**Values and Variables.** The absence of type declarations in Icon has far-reaching implications. Since any variable may have a value of any type and the type may change from time to time during program execution, there must be a way of representing values uniformly. This is a significant challenge in a language with a wide variety of types ranging from integers to co-expressions. Heterogeneous structures follow as a natural consequence of the lack of type declarations.

In one sense, the absence of type declarations simplifies the implementation: there is not much that can be done about types during program translation (compilation), and some of the work that is normally performed by conventional compilers can be avoided. The problems do not go away, however – they just move to another part of the implementation, since run-time type checking is required. Automatic type conversion according to context goes hand-in-hand with type checking.

**Storage Management.** Since strings and structures are created during program execution, rather than being declared, the space for them must be allocated as needed at run time. This implies, in turn, some mechanism for reclaiming space that has been allocated but which is no longer needed—"garbage collection." These issues are complicated by the diversity of types and sizes of objects, the lack of any inherent size limitations, and the possibility of pointer loops in circular structures.

**Strings.** Independent of storage-management considerations, strings require special attention in the implementation. The emphasis of Icon is on string processing, and it is necessary to be able to process large amounts of string data sufficiently. Strings may be very long and many operations produce substrings of other strings. The repertoire of string analysis and string synthesis functions is large. All this adds up to the need for a well-designed and coherent mechanism for handling strings.

**Structures.** Icon's unusual structures, with sophisticated access mechanisms, also pose problems. In particular, structures that can change in size and can grow without limit require different implementation approaches than static structures of fixed size and organization.

The flexibility of positional, stack, and queue access mechanisms for lists requires compromises to balance efficient access for different uses. Sets of values with arbitrary types, combined with a range of set operations, pose non-trivial implementation problems. Tables are similar to sets, but require additional attention because of the implicit way that elements are added.

**Procedures and Functions.** Since procedures and functions are values, they must be represented as data objects. More significantly, the meaning of a function call cannot, in general, be determined when a program is translated. The expression `write(s)` may write a string or it may do something else, depending on whether or not `write` still has its initial value. Such meanings must,

instead, be determined at run time.

**Polymorphic Operations.** Although the meanings of operations cannot be changed during program execution in the way that the meanings of calls can, several operations perform different computations depending on the types of their operands. Thus,  $x[i]$  may subscript a string, a list, or a table.

The meanings of some operations also depend on whether they occur in an assignment or a dereferencing context. For example, if  $s$  has a string value, assignment to  $s[i]$  is an abbreviation for a concatenation followed by an assignment to  $s$ , while if  $s[i]$  occurs in a context where its value is needed, it is simply a substring operation. Moreover, the context cannot, in general, be determined at translation time.

The way subscripting operations are specified in Icon offers considerable convenience to the programmer at the expense of considerable problems for the implementer.

**Expression Evaluation.** Generators and goal-directed evaluation present obvious implementation problems. There is a large body of knowledge about the implementation of expression evaluation for conventional languages in which expressions always produce a single result, but there is comparatively little knowledge about implementing expressions that produce results in sequence.

While there are languages in which expressions can produce more than one result, this capability is limited to specific contexts, such as pattern matching, or to specific control structures or data objects.

In Icon, generators and goal-directed evaluation are general and pervasive and apply to all evaluation contexts and to all types of data. Consequently, their implementation requires a fresh approach. The mechanism also has to handle the use of failure to drive control structures and must support novel control structures, such as alternation and limitation. Efficiency is a serious concern, since whatever mechanism is used to implement generators is also used in conventional computational situations in which only one result is needed.

**String Scanning.** String scanning is comparatively simple. The subject and position — "state variables" — have to be saved at the beginning of string scanning and restored when it is completed. Actual string analysis and matching follow trivially from generators and goal-directed evaluation.

**Co-Expressions.** Co-expressions, which are only relevant because of the expression-evaluation mechanism of Icon, introduce a whole new set of complexities. Without co-expressions, the results that a generator can produce are limited to its site in the program. Control backtracking is limited syntactically, and its scope can be determined during program translation. With co-expressions, a generator in a state of suspension can be activated at any place and time during program execution.

RETROSPECTIVE: Icon has a number of unusual features that are designed to facilitate programming, and it has an extensive repertoire of string and structure operations. One of Icon's notable characteristics is the freedom from translation-time constraints and the ability to specify and change the meanings of operations at run time. This run-time flexibility is valuable to the programmer, but it places substantial burdens on the implementation—and also makes it interesting.

At the top level, there is the question of how actually to carry out some of the more sophisticated

operations. Then there are questions of efficiency, both in execution speed and storage utilization. There are endless possibilities for alternative approaches and refinements.

It is worth noting that many aspects of the implementation are relatively independent of each other and can be approached separately. Operations on strings and structures are largely disjoint and can, except for general considerations of the representation of values and storage management, be treated as independent problems.

The independence of expression evaluation from other implementation considerations is even clearer. Without generators and goal-directed evaluation, Icon would be a fairly conventional high-level string and structure processing language, albeit one with interesting implementation problems. On the other hand, generators and goal-directed evaluation are not dependent in any significant way on string and structure data types. Generators, goal-directed evaluation, and related control structures could just as well be incorporated in a programming language emphasizing numerical computation. The implementation problems related to expression evaluation in the two contexts are largely the same.

While untyped variables and automatic storage management have pervasive effects on the overall implementation of Icon, there are several aspects of Icon that are separable from the rest of the language and its implementation. Any specific data structure, string scanning, or co-expressions could be eliminated from the language without significantly affecting the rest of the implementation. Similarly, new data structures and new access mechanisms could be added without requiring significant modifications to the balance of the implementation.

## EXERCISES

**2.1** What is the outcome of the following expression if the file *f* contains a line consisting of “end”, or if it does not?

```
while line := read(f) do
    if line == "end" then break
    else write(line)
```

**2.2** What does

```
write("hello" | "howdy")
```

write?

**2.3** What is the result of evaluating the following expression:

```
1(1 to 3) > 10
```

**2.4** Explain the rationale for dereferencing of variables when a procedure call returns.

**2.5** Give an example of a situation in which it cannot be determined until run time whether a string subscripting expression is used in an assignment or a dereferencing context.

## Chapter 3

# Organization of the Implementation

**PERSPECTIVE:** Many factors influence the implementation of a programming language. The properties of the language itself, of course, are of paramount importance. Beyond this, goals, resources, and many other factors may affect the nature of an implementation in significant and subtle ways.

In the case of the implementation of Icon described here, several unusual factors deserve mention. To begin with, Icon's origins were in a research project, and its implementation was designed not only to make the language available for use but also to support further language development. The language itself was less well defined and more subject to modification than is usually the case with an implementation. Therefore, flexibility and ease of modification were important implementation goals.

Although the implementation was not a commercial enterprise, neither was it a toy or a system intended only for a few "friendly users." It was designed to be complete, robust, easy to maintain, and sufficiently efficient to be useful for real applications in its problem domain.

Experience with earlier implementations of SNOBOL4, SL5, and the Ratfor implementation of Icon also influenced the implementation that is described here. They provided a repertoire of proven techniques and a philosophy of approach to the implementation of a programming language that has novel features.

The computing environment also played a major role. The implementation started on a PDP-11/70 running under UNIX. The UNIX environment (Ritchie and Thompson 1978), with its extensive range of tools for program development, influenced several aspects of the implementation in a direct way. C (Kernighan and Ritchie 1978) is the natural language for writing such an implementation under UNIX, and its use for the majority of Icon had pervasive effects, which are described throughout this book. Tools, such as the Yacc parser-generator (Johnson 1975), influenced the approach to the translation portion of the implementation.

Since the initial work was done on a PDP-11/70, with a user address space of only 128K bytes (combined instruction and data spaces), the size of the implementation was a significant concern. In particular, while the Ratfor implementation of Icon fit comfortably on computers with large address spaces, such as the DEC-10, CDC Cyber, and IBM 370, this implementation was much too large

to fit on a PDP-11/70.

### 3.1 The Icon Virtual Machine

The implementation of Icon is organized around a virtual machine (Newey, Poole, and Waite 1972; Griswold 1977). Virtual machines, sometimes called abstract machines, serve as software design tools for implementations in which the operations of a language do not fit a particular computer architecture or where portability is a consideration and the attributes of several real computer architectures can be abstracted in a single common model. The expectation for most virtual machine models is that a translation will be performed to map the virtual machine operations onto a specific real machine. A virtual machine also provides a basis for developing an operational definition of a programming language in which details can be worked out in concrete terms.

During the design and development phases of an implementation, a virtual machine serves as an idealized model that is free of the details and idiosyncrasies of any real machine. The virtual machine can be designed in such a way that treatment of specific, machine-dependent details can be deferred until it is necessary to translate the implementation of the virtual machine to a real one.

Icon's virtual machine only goes so far. Unlike the SNOBOL4 virtual machine (Griswold 1972), it is incomplete and characterizes only the expression-evaluation mechanism of Icon and computations on Icon data. It does not, *per se*, include a model for the organization of memory. There are many aspects of the Icon run-time system, such as type checking, storage allocation and garbage collection, that are not represented in the virtual machine. Instead Icon's virtual machine serves more as a guide and a tool for organizing the implementation than it does as a rigid structure that dominates the implementation.

### 3.2 Components of the Implementation

There are three major components of the virtual machine implementation of Icon: a translator, a linker, and a run-time system. The translator and linker are combined to form a single executable program, but they remain logically independent.

The translator plays the role of a compiler for the Icon virtual machine. It analyzes source programs and converts them to virtual machine instructions. The output of the translator is called *ucode*. Ucode is represented as ASCII which is helpful in debugging the implementation.

The linker combines one or more ucode files into a single program for the virtual machine. This allows programs to be written and translated in a number of modules, and it is particularly useful for giving users access to pretranslated libraries of Icon procedures. The output of the linker, called *icode*, is in binary format for compactness and ease of processing by the virtual machine. Ucode and icode instructions are essentially the same, differing mainly in their format.

Translating and linking are done in two phases:

These phases can be performed separately. If only the first phase is performed, the result is ucode, which can be saved and linked at another time.

The run-time system consists of an interpreter for icode and a library of support routines to carry out the various operations that may occur when an Icon program is executed. The interpreter serves, conceptually, as a software realization of the Icon virtual machine. It decodes icode instructions and their operands and carries out the corresponding operations.

It is worth noting that the organization of the Icon system does not depend in any essential way on the use of an interpreter. In fact, in the early versions of this implementation, the linker produced assembly-language code for the target machine. That code then was assembled and loaded with the run-time library. On the surface, the generation of machine code for a specific target machine rather than for a virtual machine corresponds to the conventional compilation approach. However, this is somewhat of an illusion, since the machine code consists largely of calls to run-time library routines corresponding to virtual machine instructions. Execution of machine code in such an implementation therefore differs only slightly from interpretation, in which instruction decoding is done in software rather than in hardware. The difference in speed in the case of Icon is relatively minor.

An interpreter offers a number of advantages over the generation of machine code that offset the small loss of efficiency. The main advantage is that the interpreter gets into execution very quickly, since it does not require a loading phase to resolve assembly-language references to library routines. Icode files also are much smaller than the executable binary files produced by a loader, since the run-time library does not need to be included in them. Instead, only one sharable copy of the run-time system needs to be resident in memory when Icon is executing.

### 3.3 The Translator

The translator that produces ucode is relatively conventional. It is written entirely in C and is independent of the architecture of the target machine on which Icon runs. Ucode is portable from one target machine to another.

The translator consists of a lexical analyzer, a parser, a code generator, and a few support routines. The lexical analyzer converts a source-language program into a stream of tokens that are provided to the parser as they are needed. The parser generates abstract syntax trees on a per-procedure basis. These abstract syntax trees are in turn processed by the code generator to produce ucode. The parser is generated automatically by Yacc from a grammatical specification. Since the translator is relatively conventional and the techniques that it uses are described in detail elsewhere

(Aho, Lam, Sethi, and Ullman 2006), it is not discussed here.

There is one aspect of lexical analysis that deserves mention. The body of an Icon procedure consists of a series of expressions that are separated by semicolons. However, these semicolons usually do not need to be provided explicitly, as illustrated by examples in Chapter 2. Instead, the lexical analyzer performs semicolon insertion. If a line of a program ends with a token that is legal for ending an expression, and if the next line begins with a token that is legal for beginning an expression, the lexical analyzer generates a semicolon token between the lines. For example, the two lines

```
i := j + 3
write(i)
```

are equivalent to

```
i := j + 3;
write(i)
```

since an integer literal is legal at the end of an expression and an identifier is legal at the beginning of an expression.

If an expression spans two lines, the place to divide it is at a token that is not legal at the end of a line. For example,

```
s1 := s2 ||
s3
```

is equivalent to

```
s1 := s2 || s3
```

No semicolon is inserted, since `||` is not legal at the end of an expression.

### 3.4 The Linker

The linker reads ucode files and writes icode files. An icode file consists of an executable header that loads the run-time system, descriptive information about the file, operation codes and operands, and data specific to the program. The linker, like the translator, is written entirely in C. While conversion of ucode to icode is largely a matter of reformatting, the linker performs two other functions.

### 3.4.1 Scope Resolution

The scope of an undeclared identifier in a procedure depends on global declarations (explicit or implicit) in the program in which the procedure occurs. Since the translator in general operates on only one module of a program, it cannot resolve the scope of undeclared identifiers, because not all global scope information is contained in any one module. The linker, on the other hand, processes all the modules of a program, and hence it has the task of resolving the scope of undeclared identifiers.

An identifier may be global for several reasons:

- As the result of an explicit global declaration.
- As the name in a record declaration.
- As the name in a procedure declaration.
- As the name of a built-in function.

If an identifier with no local declaration falls into one of these categories, it is global. Otherwise it is local.

### 3.4.2 Construction of Run-Time Structures

A number of aspects of a source-language Icon program are represented at run time by various data structures. These structures are described in detail in subsequent chapters. They include procedure blocks, strings, and blocks for cset and real literals that appear in the program.

This data is represented in ucode in a machine-independent fashion. The linker converts this information into binary images that are dependent on the architecture of the target computer.

## 3.5 The Run-Time System

Most of the interesting aspects of the implementation of Icon reside in its run-time system. This run-time system is written mostly in C, although there are a few lines of assembly-language code for checking for arithmetic overflow and for co-expressions. The C portion is mostly machine-independent and portable, although some machine-specific code is needed for some idiosyncratic computer architectures and to interface some operating-system environments.

There are two main reasons for concentrating the implementation in the run-time system:

- Some features of Icon do not lend themselves to translation directly into executable code for the target machine, since there is no direct image for them in the target-machine architecture. The target machine code necessary to carry out these operations therefore is too large to place

in line; instead, it is placed in library routines that are called from in-line code. Such features range from operations on structures to string scanning.

- Operations that cannot be determined at translation time must be done at run time. Such operations range from type checking to storage allocation and garbage collection.

The run-time system is logically divided into four main parts: initialization and termination routines, the interpreter, library routines called by the interpreter, and support routines called by library routines.

**Initialization and Termination Routines.** The initialization routine sets up regions in which objects created at run time are allocated. It also initializes some structures that are used during program execution. Once these tasks are completed, control is transferred to the Icon interpreter.

When a program terminates, either normally or because of an error, termination routines flush output buffers and return control to the operating system.

**The Interpreter.** The interpreter analyzes icode instructions and their operands and performs corresponding operations. The interpreter is relatively simple, since most complex operations are performed by library routines. The interpreter itself is described in Chapter 8.

**Library Routines.** Library routines are divided into three categories, depending on the way they are called by the interpreter: routines for Icon operators, routines for Icon built-in functions, and routines for complicated virtual machine instructions.

The meanings of operators are known to the translator and linker, and hence they can be called directly. On the other hand, the meanings of functions cannot be determined until they are executed, and hence they are called indirectly.

**Support Routines.** Support routines include storage allocation and garbage collection, as well as type checking and conversion. Such routines typically are called by library routines, although some are called by other support routines.

**RETROSPECTIVE:** Superficially, the implementation of Icon appears to be conventional. An Icon program is translated and linked to produce an executable binary file. The translator and linker *are* conventional, except that they generate code and data structures for a virtual machine instead of for a specific computer.

The run-time system dominates the implementation and plays a much larger role than is played by run-time systems in conventional implementations. This run-time system is the focus of the remainder of this book.

## EXERCISES

**3.1** Explain why there is only a comparatively small difference in execution times between a version of Icon that generates assembly-language code and one that generates virtual machine code that is interpreted.

**3.2** List all the tokens in the Icon grammar that are legal as the beginning of an expression and as the end of an expression. Are there any tokens that are legal as both? As neither?

**3.3** Is a semicolon inserted by the lexical analyzer between the following two program lines?

```
s1 := s2  
|| s3
```

**3.4** Is it possible for semicolon insertion to introduce syntactic errors into a program that would be syntactically correct without semicolon insertion?

# Chapter 4

## Values and Variables

PERSPECTIVE: No feature of the Icon programming language has a greater impact on the implementation than untyped variables — variables that have no specific type associated with them. This feature originated in Icon's predecessors as a result of a desire for simplicity and flexibility.

The absence of type declarations reduces the amount that a programmer has to learn and remember. It also makes programs shorter and (perhaps) easier to write. The flexibility comes mainly from the support for heterogeneous aggregates. A list, for example, can contain a mixture of strings, integers, records, and other lists. There are numerous examples of Icon programs in which this flexibility leads to programming styles that are concise and simple. Similarly, "generic" procedures, whose arguments can be of any type, often are useful, especially for modeling experimental language features.

While these facilities can be provided in other ways, such as by C's union construct, Icon provides them by the *absence* of features, which fits with the philosophy of making it easy to write good programs rather than hard to write bad ones.

The other side of the coin is that the lack of type declarations for variables makes it impossible for the translator to detect most type errors and defers type checking until the program is executed. Thus, a check that can be done only once at translation time in a language with a strong compile-time type system must be done repeatedly during program execution in Icon. Furthermore, just as the Icon translator cannot detect most type errors, a person who is writing or reading an Icon program does not have type declarations to help clarify the intent of the program.

Icon also converts arguments to the expected type where possible. This feature is, nevertheless, separable from type checking; Icon could have the latter without the former. However, type checking and conversion are naturally intertwined in the implementation.

As far as the implementation is concerned, untyped variables simplify the translator and complicate the run-time system. There is little the translator can do about types. Many operations are polymorphic, taking arguments of different types and sometimes performing significantly different computations, depending on those types. Many types are convertible to others. Since procedures are data values and may change meaning during program execution, there is nothing the translator

can know about them. For this reason, the translator does not attempt any type checking or generate any code for type checking or conversion. All such code resides in the run-time routines for the functions and operations themselves.

There is a more subtle way in which untyped variables influence the implementation. Since any variable can have any type of value at any time, and can have different types of values at different times, all values must be the same size. Furthermore, Icon's rich repertoire of data types includes values of arbitrary size—lists, tables, procedures, and so on.

The solution to this problem is the concept of a *descriptor*, which either contains the data for the value, if it is small enough, or else contains a pointer to the data if it is too large to fit into a descriptor. The trick, then, is to design descriptors for all of Icon's data types, balancing considerations of size, ease of type testing, and efficiency of accessing the actual data.

## 4.1 Descriptors

Since every Icon value is represented by a descriptor, it is important that descriptors be as small as possible. On the other hand, a descriptor must contain enough information to determine the type of the value that it represents and to locate the actual data. Although values of some types cannot possibly fit into any fixed-size space, it is desirable for frequently used, fixed-sized values, such as integers, to be stored in their descriptors. This allows values of these types to be accessed directly and avoids the need to provide storage elsewhere for such values.

If Icon were designed to run on only one kind of computer, the size and layout of the descriptor could be tailored to the architecture of the computer. Since the implementation is designed to run on a wide range of computer architectures, Icon takes an approach similar to that of C. Its descriptor is composed of “words,” which are closely related to the concept of a word on the computer on which Icon is implemented. One word is not large enough for a descriptor that must contain both type information and an integer or a pointer. Therefore, a descriptor consists of two words, which are designated as the *d-word* and the *v-word*, indicating that the former contains descriptive information, while the latter contains the value

The dotted line between the two words of a descriptor is provided for readability. A descriptor is merely two words, and the fact that these two words constitute a descriptor is a matter of context.

The v-word of a descriptor may contain either a value, such as an integer, or a pointer to other data. In C terms, the v-word may contain a variety of types, including both ints and pointers. On many computers, C ints and C pointers are the same size. For some computers, however, C compilers have a memory-model in which integers are smaller than pointers, which must allow access to a large amount of memory. In this situation, the C long or long long type are the same size

as C pointers. There are computers with many different word sizes, but the main considerations in the implementation of Icon are the accommodation of computers with 32- and 64-bit words and the large-memory model, in which pointers are larger than integers. In the large-memory model, a v-word must accommodate the largest of the types.

The d-words of descriptors contain a type code (a small integer) in their least significant bits and flags in their most significant bits. There are twelve type codes that correspond to source-language data types:

<i>data type</i>	<i>type code</i>
null	null
integer	integer or long
real number	real
cset	cset
file	file
procedure	proc
list	list
set	set
table	table
record	record
co-expression	coexpr

Other type codes exist for internal objects, which are on a par with source-language objects, from an implementation viewpoint, but which are not visible at the source-language level. The actual values of these codes are not important, and they are indicated in diagrams by their type code names.

### 4.1.1 Strings

There is no type code for strings. They have a special representation in which the d-word contains the length of the string (the number of characters in it) and the v-word points to the first character in the string:

String descriptors are called *qualifiers*. In order to make qualifiers more intelligible in the diagrams that follow, a pointer to a string is followed by the string in quotation marks rather than by an address. For example, the qualifier for "hello" is depicted as

In order to distinguish qualifiers from other descriptors with type codes that might be the same as a string length, all descriptors that are not qualifiers have an *n* flag in the most significant bit of the *d*-word. The *d*-words of qualifiers do not have this *n* flag, and string lengths are restricted to prevent their overflow into this flag position, the most significant bit of a 32- or 64-bit *d*word.

### 4.1.2 The Null Value

A descriptor for the null value has the form

As explained previously, the *n* flag occurs in this and all other descriptors that are not qualifiers so that strings can be easily and unambiguously distinguished from all other kinds of values. The value in the *v*-word could be any constant value, but zero is useful and easily identified—and suggests "null."

In the diagrams that follow, a null block-pointer is represented as

Icon version 6 used descriptors in blocks to refer to other blocks (see section 4.2). Subsequent versions switched to using pointers.

### 4.1.3 Integers

Icon supports word-size integers at least 32-bits in size. Such integers therefore are typically *C* longs, depending on the computer architecture. As long as it fits, the value of an Icon integer is stored in the *v*-word of its descriptor. For example, the integer 13570 is represented by

Note that the *n* flag distinguishes this descriptor from a string whose first character might be at the address 13570 and whose length might have the same value as the type code for integer.

An Icon integer that fits in the *v*-word is stored there. An integer that is too large to fit into a word is stored in a data structure that is pointed to by the *v*-word, as illustrated in the next section. The two representations of integers are distinguished by different internal type codes: *integer* for integers that are contained in the *v*-words of their descriptors and *lrgint* for integers that are contained in blocks pointed to by the *v*-words of their descriptors. Thus, there are two internal types for one source-language data type.

## 4.2 Blocks

All other types of Icon data are represented by descriptors with v-words that point to blocks of words. These blocks have a comparatively uniform structure that is designed to facilitate their processing during garbage collection.

The first word of every block, called its *title*, contains a type code. This type code is the same code that is in the type-code portion of the d-word of a descriptor that points to the block. Some blocks are fixed in size for all values of a given type. For example, on a computer with 32-bit words, the source language integer 5,000,000,000 is stored in a large integer block:

The p flag in the descriptor indicates that the v-word contains a pointer to a block.

Blocks of some other types, such as record blocks, vary in size from value to value, but any one block is fixed in size and never grows or shrinks. If the type code in the title does not determine the size of the block, the second word in the block contains its size in bytes. In the diagrams that follow, the sizes of blocks are given for computers with 32-bit words. The diagrams would be slightly different for computers with 16-bit words.

Records, which differ in size depending on how many fields they have, are examples of blocks that contain their sizes. For example, given the record declaration

record complex(r, i)

and

point := complex(1, 3)

the value of point is

The record-constructor block contains information that is needed to resolve field references.

The *id* field is present in many blocks. Its purpose is to distinguish between different blocks of the same type (for example, it is used in the computation of the hash value that determines

where to place a value in a table — see section 7.3 for details). The *id* field is also printed out by diagnostic routines; it is incremented for each block created. The runtime system maintains separate *id* counters for blocks of different types.

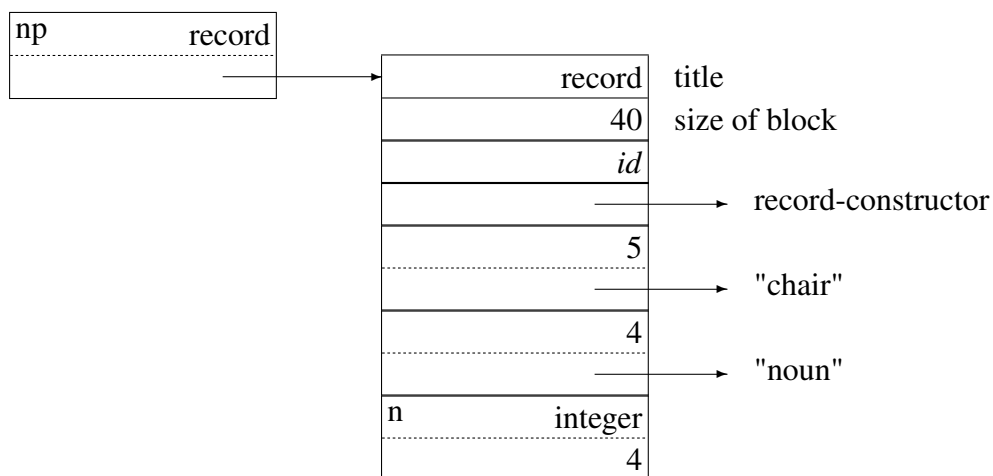

With the declaration

```
record term(value, code, count)
```

and

```
word := term("chair", "noun", 4)
```

the value of word is:

As illustrated by these examples, blocks may contain descriptors as well as non-descriptor data. Non-descriptor data comes first in the block, followed by any descriptors, as illustrated by the preceding figure. The location of the first descriptor in a block is constant for all blocks of a given type, which facilitates garbage collection. Block-pointers may be placed anywhere before the descriptors, but the garbage collector expects them to be contiguous and in a fixed place for all blocks of a given type.

Blocks for the remaining types are described in subsequent chapters.

## 4.3 Variables

Variables are represented by descriptors, just as values are. This representation allows values and variables to be treated uniformly in terms of storage and access. Variables for identifiers point to descriptors for the corresponding values. Variables always point to descriptors for values, never to other variables. For example, if

```
s := "hello"
```

then a variable for *s* has the form

The *v* flag distinguishes descriptors for variables from descriptors for values.

The values of local identifiers are kept on a stack, while the values of global and static identifiers are located at fixed places in memory. Variables that point to the values of identifiers are created by icode instructions that correspond to the use of the identifiers in the program.

Some variables, such as record field references, are computed. A variable that references a value in a data structure points to the start of the data structure. The least-significant bits of the *d*-word for such a variable contain the offset, in *words*, of the value descriptor from the top of the block in which the value is contained. The use of words, rather than bytes, allows larger offsets, which is important for computers with 16-bit words. For example, the variable *word.count* for the record given in the preceding section is

Note that the variable *word.count* cannot be determined at translation time, since the type of *word* is not known then and different record types could have count fields in different positions.

### 4.3.1 Operations on Variables

There are two fundamentally different contexts in which a variable can be used: *dereferencing* and *assignment*.

Suppose, as shown previously, that the value of the identifier *s* is the string "hello". Then a variable descriptor that points to the value of *s* and the corresponding value descriptor for "hello" have the following relationship:

In an expression such as *write(s)*, *s* is dereferenced by fetching the descriptor pointed to by the *v*-word of the variable.

In the case of assignment, as in

`s := 13570`

the value descriptor pointed to by the v-word of the variable descriptor changed:

These operations on variables correspond to indirect load and store instructions of a typical computer.

### 4.3.2 Special Variables

Icon has several variables with special properties that complicate assignment and dereferencing. Consider, for example, the keyword `&trace`. Its value must always be an integer. Consequently, in an assignment such as

`&trace := expr`

the value produced by *expr* must be checked to be sure that it is an integer. If it is not, an attempt is made to convert it to an integer, so that in

`&trace := "1"`

the value assigned to `&trace` is the integer 1, not the string "1".

A naive way to handle assignment to these keywords is to check every variable during assignment to see whether it is one that requires special processing. This would place a significant computational burden on every assignment. Instead, Icon divides variables into two classes: *ordinary* and *trapped*. Ordinary variables point to their values as illustrated previously and require no special processing. Trapped variables, so called because their processing is "trapped," are distinguished from ordinary variables by a *t* flag. Thus, assignment only has to check a single flag to separate the majority of variables from those that require special processing.

#### 4.3.2.1 Trapped Variables

Icon Version 6 used the trapped variable approach to handle assignments to keywords, substrings and table elements. Subsequent versions of Icon (and Unicon) no longer use trapped variables for assignments to keywords: instead keyword variables have different types to "normal" variables.

Trapped variables are still in use however to deal with the special processing required for assignment to sub-strings and table elements — see section 12.2.

It is worth noting that the more conventional approach to handling the problem of assignment to keywords and other special cases is to compile special code if the special case occurs an assignment context. It is not always possible, however, to determine the context in which a variable is used in Icon. Assume `tb` is a table and consider a procedure of the form

```
procedure tabvar(n)
...
return tb[n]
end
```

The semantics of Icon dictate that the result returned in this case should be a variable, not just its value, so that it is possible to write an expression such as

```
tabvar(5) := 10
```

which has the effect of assigning the value 10 to `tb[5]`.

The translator has no way of knowing that an assignment to the call `tabvar(5)` is equivalent to an assignment to `tb[5]`. In fact, the translator cannot even determine that the value of `tabvar` will be a function when the previous assignment is performed, much less that it will be the procedure given earlier. The trapped-variable mechanism provides a way to handle uniformly all such situations.

#### 4.3.2.2 Keyword Variables

Trapped variables are especially useful when dealing with cases where a variable sometimes needs special treatment and sometimes not. But keywords *always* require special treatment, so they have their own types, distinct from the everyday numerical and string types. The keyword type codes are defined symbolically (values for other types are given in section 4.4.3).

```
#define T_Kywdint      20      /* integer keyword */
#define T_Kywdpos      21      /* keyword &pos */
#define T_Kywdsubj     22      /* keyword &subject */
#define T_Kywdwin      23      /* keyword &window */
#define T_Kywdstr       24      /* string keyword */
#define T_Kywdevent     25      /* keyword &eventsource, etc. */
```

There are four keyword variables that require special processing for assignment: `&trace`, `&random`, `&subject`, and `&pos`. The keyword `&random` is treated in essentially the same way that `&trace` is. Assignment to `&subject` requires a string value and has the side effect of assigning the value 1 to `&pos`. Assignment to `&pos` is even more complicated: not only must the value assigned be an integer, but if it is not positive, it must also be converted to the positive equivalent with respect

to the length of &subject. In any event, if the value in the assignment to &pos is not in the range of &subject, the assignment fails. Dereferencing these keywords, on the other hand, requires no special processing.

See section 12.2 for a further discussion of keyword variables

## 4.4 Descriptors and Blocks in C

Descriptors and blocks of data are described and depicted abstractly in the previous sections of this chapter. In order to understand the implementation of some aspects of Icon, it is helpful to examine the C code that actually defines and manipulates data.

The following sections illustrate typical C declarations for the structures used in the implementation of Icon. Some of the terminology and operations that appear frequently in the C code are included as well. Other operations are introduced in subsequent chapters. as they are needed.

### 4.4.1 Descriptors

As mentioned in Sec. 4.1, for C compilers in which ints and pointers are the same size, the size of a word is the size of an int, while if pointers are larger than ints, the size of a word is the size of a long, or a long long. The difference between these models of memory is handled by typedefs under the control of conditional compilation. Two constants that characterize the sizes are defined: IntBits and WordBits. These sizes are used to select appropriate definitions for signed and unsigned words. The fact that on some 64-bit C compilers a long is only 32 bits, while on others it is 64 bits, complicates matters. The symbol LongLongWord indicates this situation.

```
#if IntBits != WordBits
    #ifndef LongLongWord
        typedef long long int word;
        typedef unsigned long long int uword;
    #else
        typedef long int word;
        typedef unsigned long uword;
    #endif
#else
    /* IntBits != WordBits */
    typedef int word;
    typedef unsigned int uword;
#endif
```

A descriptor is declared as a structure:

```

struct descrip { /* descriptor */
    word dword; /* type field */
    union {
        word integr; /* integer value */
#ifdef DescriptorDouble
        double realval;
#endif
        char *sptr; /* pointer to character string */
        union block *bptr; /* pointer to a block */
        struct descrip *dptr; /* pointer to a descriptor */
    } vword;
};

```

The v-word of a descriptor is a union that reflects its various uses: an integer, a pointer to a string, a pointer to a block, or a pointer to another descriptor (in the case of a variable).

#### 4.4.2 Blocks

Each block type has a structure declaration. For example, the declaration for record blocks is

```

struct b_record {          /* record block */
    word title;             /* T_Record */
    word blksize;           /* size of block */
    word id;                /* identification number */
    union block *recdesc;   /* pointer to record constructor */
    struct descrip fields[1]; /* fields */
};

```

Blocks for records vary in size, depending on the number of fields declared for the record type. The size of 1 in

```
struct descrip fields[1];
```

is provided to satisfy the C compiler. Actual blocks for records are constructed at run time in a region that is managed by Icon's storage allocator. Such blocks conform to the previous declaration, but the number of fields varies. The declaration provides a means of accessing portions of such blocks from C.

The declaration for substring trapped-variable blocks is

```

struct b_tvsubs {          /* substring trapped variable block */
    word title;            /* T_Tvsubs */
    word sslen;            /* length of substring */
    word sspos;            /* position of substring */
    struct descrip ssvar;   /* variable that substring is from */
};

```

Note that the title fields of `b_record` and `b_tvsubs` contain type codes, as indicated in previous diagrams. The second field of `b_record` is a size as mentioned previously, but `b_tvsubs` has no size field, since all substring trapped-variable blocks are the same size, which therefore can be determined from their type.

The block union given in the declaration of `struct descrip` consists of a union of all block types:

```

union block {
    struct b_real realblk;
    struct b_cset cset;
    struct b_file file;
    struct b_proc proc;
    struct b_list list;
    struct b_lelem lelem;
    struct b_table table;
    struct b_telem telem;
    struct b_set set;
    struct b_selem selem;
    struct b_record record;
    struct b_tvsubs tvsubs;
    struct b_tvtbl tvtbl;
    struct b_refresh refresh;
    struct b_coexpr coexpr;
    struct b_externl externl;
    struct b_slots slots;
    struct b_bignum bignumblk;
};

```

Note that there are several kinds of blocks in addition to those that correspond to source-language data types.

### 4.4.3 Defined Constants

The type codes are defined symbolically:

```

#define T_Null      0
#define T_Integer   1
#define T_Lrgint    2
#define T_Real      3
#define T_Cset      4
#define T_File      5
#define T_Proc      6
#define T_Record    7
#define T_List      8
#define T_Lelem     9
#define T_Set       10
#define T_Selem     11
#define T_Table     12
#define T_Telem     13
#define T_Tvtbl     14
#define T_Slots     15
#define T_Tvsubs    16
#define T_Refresh   17
#define T_Coexpr    18
#define T_External  19

```

The type codes in diagrams are abbreviated, as indicated by previous examples.

The defined constants for d-word flags are

```

n    F_Nqual
p    F_Ptr
v    F_Var
t    F_Tvar

```

The values of these flags depend on the word size of the computer.

The d-words of descriptors are defined in terms of flags and type codes:

```

#define D_Null      (T_Null | F_Nqual)
#define D_Integer   (T_Integer | F_Nqual)
#define D_Lrgint    (T_Lrgint | F_Ptr | F_Nqual)
#define D_Real      (T_Real | F_Ptr | F_Nqual)
#define D_Cset      (T_Cset | F_Ptr | F_Nqual)
#define D_File      (T_File | F_Ptr | F_Nqual)
#define D_Proc      (T_Proc | F_Ptr | F_Nqual)
#define D_List      (T_List | F_Ptr | F_Nqual)

```

```

#define D_Table      (T_Table | F_Ptr | F_Nqual)
#define D_Set        (T_Set | F_Ptr | F_Nqual)
#define D_Selem      (T_Selem | F_Ptr | F_Nqual)
#define D_Record     (T_Record | F_Ptr | F_Nqual)
#define D_Telem      (T_Telem | F_Ptr | F_Nqual)
#define D_Lelem      (T_Lelem | F_Ptr | F_Nqual)
#define D_Tvsubs     (T_Tvsubs | D_Tvar)
#define D_Tvtbl      (T_Tvtbl | D_Tvar)
#define D_Coexpr      (T_Coexpr | F_Ptr | F_Nqual)
#define D_Refresh    (T_Refresh | F_Ptr | F_Nqual)
#define D_Var        (F_Var | F_Nqual | F_Ptr)
#define D_Tvar       (D_Var | F_Tvar)

```

As indicated previously, flags, type codes, and d-words are distinguished by the prefixes F\_, T\_, and D\_, respectively.

#### 4.4.4 RTL Coding

Since the optimizing compiler was introduced in versions 8 and 9 of Icon, the routines for the run-time system use an extended C syntax called RTL (for Run-Time Language) that encodes the type information for arguments and results. Some of these are illustrated by the RTL function for the Icon operator \*x, which produces the size of x:

```

operator{1} * size(x)
abstract { return integer }
type_case x of {
  string: inline { return C_integer StrLen(x); }
  list: inline { return C_integer BlkD(x,List)->size; }
  table: inline { return C_integer BlkD(x,Table)->size; }
  set: inline { return C_integer BlkD(x,Set)->size; }
  cset: inline {
    register word i = BlkD(x,Cset)->size;
    if (i < 0) i = cssize(&x);
    return C_integer i;
  }
  ...
  default: {
    /*
     * Try to convert it to a string.
     */

```

```

        if !cnv:tmp_string(x) then
            runerr(112, x); /* no notion of size */
        inline {
            return C_integer StrLen(x);
        }
    }
end

```

operator is an RTL construct that performs several operations. One of these operations is to provide a C function declaration. Since the function is called by the interpreter, the header is somewhat different from what it would be if size were called directly. The details are described in Chapter 8.

The arguments of the Icon operation are referred to via named descriptors, such as *x*. The result that is produced is also a descriptor.

RTL extends C's return statement to include type information, with which the d-word of the return value is set to *D\_Integer*, since the returned value is a *C\_integer*. Next, the *type\_case* selects different branches of code depending on the type of *x*. In the generated code there is a test to determine if descriptor *x* holds a qualifier. *Qual()* is a macro that is defined as

```
#define Qual(d) (!(d).dword & F_Nqual)
```

If *x* is a qualifier, its length is placed in the v-word of the return value descriptor, using the macros *IntVal* and *StrLen*, which are defined as

```
#define IntVal(d) ((d).vword.integr)
#define StrLen(d) ((d).dword)
```

If *x* is not a qualifier, then the size depends on the type. The macro *Type()* isolates the type code

```
#define Type(d) ((d).dword & TypeMask)
```

where the value of *TypeMask* is 63, providing considerable room for additions to Icon's internal types.

For most Icon types that are represented by blocks, their source-language size is contained in their size field. The macro *BlkLoc()* accesses a pointer in the v-field of a descriptor and is defined as

```
#define BlkLoc(d) ((d).vword.bptr)
```

A more specialized macro *BlkD()* wraps uses of *BlkLoc()* and subsequent union member access, allowing descriptor-block consistency to be verified at run-time if desired.

If the type is not one of those given, the final task is an attempt to convert *x* to a string. The RTL expression *cnv:tmp\_string()* does this, using local temporary buffer. The value of *x* is changed

accordingly. A fixed-sized buffer can be used, since there is a limit to the size of a string that can be obtained by converting other types. This limit is 256, which is reached only for conversion of `&cset`. The conversion may fail, as for `*&null`, which is signaled by the return value 0 from `cnv:tmp_string()`. In this case, program execution is terminated with a run-time error message, using `runerr()`. If the conversion is successful, the size is placed in the v-word of the result, as is the case if `x` was a qualifier originally.

**RETROSPECTIVE:** Descriptors provide a uniform way of representing Icon values and variables. Since descriptors for all types of data are the same size, there are no problems with assigning different types of values to a variable—they all fit.

The importance of strings is reflected in the separation of descriptors into two classes—qualifiers and nonqualifiers—by the `n` flag. The advantages of the qualifier representation for strings are discussed in Chapter 5.

It is comparatively easy to add a new type to Icon. A new type code is needed to distinguish it from other types. If the possible values of the new type are small enough to fit into the v-word, as is the case for integers, no other data is needed. For example, the value of a character data type could be contained in its descriptor. For types that have values that are too large to fit into a v-word, pointers to blocks containing the data are placed in the v-words instead. Lists, sets, and tables are examples of data types that are represented this way. See Chapters 6 and 7.

## EXERCISES

**4.1** Give examples of Icon programs in which heterogeneous aggregates are used in significant ways.

**4.2** Design a system of type declarations for Icon so that the translator could do type checking. Give special consideration to aggregates, especially those that may change in size during program execution. Do this from two perspectives: (a) changing the semantics of Icon as little as possible, and (b) maximizing the type checking that can be done by the translator at the expense of flexibility in programming.

**4.3** Suppose that functions in Icon were not first-class values and that their meanings were bound at translation time. How much could the translator do in the way of error checking?

**4.4** Compile a list of all Icon functions and operators. Are there any that do not require argument type checking? Are there any that require type checking but not conversion? Identify those that are polymorphic. For the polymorphic ones, identify the different kinds of computations that are performed depending on the types of the arguments.

**4.5** Compose a table of all type checks and conversions that are required for Icon functions and operators.

**4.6** To what extent would the implementation of Icon be simplified if automatic type conversion were not supported? How would this affect the programmer?

**4.7** Why is it desirable for string qualifiers not to have flags and for all other kinds of descriptors to have flags indicating they are not qualifiers, rather than the other way around?

- 4.8** Is the *n* flag that distinguishes string qualifiers from all other descriptors really necessary? If not, explain how to distinguish the different types of descriptors without this flag.
- 4.9** On computers with extremely limited address space, two-word descriptors may be impractically large. Describe how one-word descriptors might be designed, discuss how various types might be represented, and describe the ramifications for storage utilization and execution speed.
- 4.10** Identify the diagrams in this chapter that would be different if they were drawn for a computer with 16-bit words. Indicate the differences.
- 4.11** There is nothing in the nature of keywords that requires them to be processed in a special way for assignment but not for dereferencing. Invent a new keyword that is a variable that requires processing when it is dereferenced. Show how to generalize the keyword trapped-variable mechanism to handle such cases.
- 4.12** List all the syntactically distinct cases in which the translator can determine whether a keyword variable is used in an assignment or dereferencing context.
- 4.13** What would be gained if special code were compiled for those cases in which the context for keyword variables could be determined?

# Chapter 5

## Strings and Csets

**PERSPECTIVE:** Several aspects of strings as a language feature in Icon have a strong influence on how they are handled by the implementation. First of all, strings are the most frequently used type of data in the majority of Icon programs. The number of different strings and the total amount of string data often are large. Therefore, it is important to be able to store and access strings efficiently.

Icon has many operations on strings—nearly fifty of them. Some operations, such as determining the size of a string, are performed frequently. The efficiency of these operations is an important issue and influences, to a considerable extent, how strings are represented.

Icon strings may be very long. Although some limitation on the maximum length of a string may be acceptable as a compromise with the architecture of the computer on which Icon is implemented (and hence considerations of efficiency), this maximum must be so large as to be irrelevant for most Icon programs.

String lengths are determined dynamically during program execution, instead of being specified statically in declarations. Much of the advantage of string processing in Icon over other programming languages comes from the automatic management of storage for strings.

Any of the 256 8-bit ASCII characters can appear in an Icon string. Even the “null” character is allowed.

Several operations in Icon return substrings of other strings. Substrings tend to occur frequently, especially in programs that analyze (as opposed to synthesize) strings.

Strings in Icon are atomic—there are no operations in Icon that change the characters in existing strings. This aspect of Icon is not obvious; in fact, there are operations that appear to change the characters in strings. The atomic nature of string operations in Icon simplifies its implementation considerably. For example, assignment of a string value to a variable need not (and does not) copy the string.

The order in which characters appear is an essential aspect of strings. There are many situations in Icon, however, where several characters have the same status but where their order is irrelevant. For example, the concepts of vowels and punctuation marks depend on set membership but not on order. Csets are provided for such situations. Interestingly, many computations can be performed

using csets that have nothing to do with the characters themselves (Griswold and Griswold 1983, pp. 181-191).

## 5.1 Strings

### 5.1.1 Representation of Strings

Although it may appear natural for the characters of a string to be stored in consecutive bytes, this has not always been so. On earlier computer architectures without byte addressing and character operations, some string-manipulation languages represented strings by linked lists of words, each word containing a single character. Such a representation seems bizarre for modern computer architectures and obviously consumes a very large amount of memory — an intolerable amount for a language like Icon.

The C programming language represents strings (really arrays of characters) by successive bytes in memory, using a zero (null) byte to indicate the end of a string. Consequently, the end of a string can be determined from the string itself, without any external information. On the other hand, determining the length of a string, if it is not already known, requires indexing through it, incrementing a counter until a null byte is found. Furthermore, and very important for a language like Icon, substrings (except terminal ones) cannot occur within strings, since every C string must end with a null byte.

Since any character can occur in an Icon string, it is not possible to use C's null-termination approach to mark ends of strings. Therefore, there is no way to detect the end of a string from the string itself, and there must be some external way to determine where a string ends. This consideration provides the motivation for the qualifier representation described in the last chapter. The qualifier provides information, external to the string itself, that delimits the string by the address of its first character and its length. Such a representation makes the computation of substrings fast and simple—and, of course, determining the length of a string is fast and independent of its length.

Note that C-style strings serve perfectly well as Icon-style strings; the null byte at the end of a C-style string can be ignored by Icon. This allows strings produced by C functions to be used by Icon. The converse is not true; in order for an Icon string to be used by C, a copy must be made with a null byte appended at the end.

Some strings are compiled into the run-time system and others, such as strings that appear as literals in a program, are contained in icode files that are loaded into memory when program execution begins. During program execution, Icon strings may be stored in work areas (usually referred to as "buffers"). Most newly created strings, however, are allocated in a common string region.

As source-language operations construct new strings, their characters are appended to the end of those already in the string region. The amount of space allocated in the string region typically in-

creases during program execution until the region is full, at which point it is compacted by garbage collection, squeezing out characters that are no longer needed. See Chapter 11 for details.

In the previous chapter, the string to which a qualifier points is depicted by an arrow followed by the string. For example, the string "the" is represented by the qualifier

The pointer to "the" is just a notational convenience. A more accurate representation is

The actual value of the v-word might be 0x569a (hexadecimal), where the character t is at memory location 0x569a, the character h is at location 0x569b, and the character e is at location 0x569c.

### 5.1.2 Concatenation

In an expression such as

`s := "hello"`

the string "hello" is contained in data provided as part of the icode file, and a qualifier for it is assigned to `s`; no string is constructed. Some operations that produce strings require the allocation of new strings. Concatenation is a typical example:

`s1 := "ab" || "cdef"`

In this expression, the concatenation operation allocates space for six characters, copies the two strings into this space, and produces a qualifier for the result:

This qualifier then becomes the value of `s1`.

There are important optimizations in concatenation. If the first argument in a concatenation is the last string in the string region, the second argument is simply appended to the end of the string region. Thus, operations of the form

`s := s || expr`

perform less allocation than operations of the form

$s := \text{expr} \parallel s$

Similarly, if the strings being concatenated are already adjacent, no concatenation need be performed. Except for these optimizations, no string construction operation attempts to use another instance of a string that may exist somewhere else in the string region. As a result,

$s1 := \text{"ab"} \parallel \text{"c"}$   
 $s2 := \text{"a"} \parallel \text{"bc"}$

produce two distinct strings:

The RTL code for the concatenation operation is

```
operator{1} || cater(x,y)
if !cnv:string(x) then
  runerr(103, x)
if !cnv:string(y) then
  runerr(103, y)

abstract {
  return string
}
body {
  CURTSTATE();

  /*
   * Optimization 1: The strings to be concatenated are
   * already adjacent in memory; no allocation is required.
   */
  if (StrLoc(x) + StrLen(x) == StrLoc(y)) {
    StrLoc(result) = StrLoc(x);
    StrLen(result) = StrLen(x) + StrLen(y);
```

```

        return result;
    }
    else if ((StrLoc(x) + StrLen(x) == strfree)
    && (DiffPtrs(strend,strfree) > StrLen(y))) {
        /*
        * Optimization 2: The end of x is at the end of the string space.
        * Hence, x was the last string allocated and need
        * not be re-allocated. y is appended to the string
        * space and the result is pointed to the start of x.
        */
        result = x;
        /*
        * Append y to the end of the string space.
        */
        Protect(alcstr(StrLoc(y),StrLen(y)), runerr(0));
        /*
        * Set the length of the result and return.
        */
        StrLen(result) = StrLen(x) + StrLen(y);
        return result;
    }

    /*
    * Otherwise, allocate space for x and y, and copy them
    * to the end of the string space.
    */
    Protect(StrLoc(result) = alcstr(NULL, StrLen(x) + StrLen(y)), runerr(0));
    memcpy(StrLoc(result), StrLoc(x), StrLen(x));
    memcpy(StrLoc(result) + StrLen(x), StrLoc(y), StrLen(y));

    /*
    * Set the length of the result and return.
    */
    StrLen(result) = StrLen(x) + StrLen(y);
    return result;
}
end

```

The function `strreq(n)` assures that there are at least `n` bytes available in the allocated string

region. See Chapter 11 for details. The function `alcstr(s, n)` allocates `n` characters and copies `s` to that space. The global variable `strfree` points to the beginning of the free space at the end of the allocated string region.

### 5.1.3 Substrings

Many string operations do not require the allocation of a new string but only produce new qualifiers. For example, if the value of `s1` is "abcdef", the substring formed by

```
s2 := s1[3:6]
```

does not allocate a new string but only produces a qualifier that points to a substring of `s1`:

In order for Icon string values to be represented in memory by substrings, it is essential that there be no Icon operation that changes the characters inside a string. As mentioned earlier, this is the case, although it is not obvious from a cursory examination of the language. C, on the other hand, allows the characters in a string to be changed. The difference is that C considers a string to be an array of characters and allows assignment to the elements of the array, while Icon considers a string to be an indivisible atomic object. It makes no more sense in Icon to try to change a character in a string than it does to try to change a digit in an integer. Thus, if

```
i := j
```

and

```
j := j + 1
```

the value of `i` does not change as a result of the subsequent assignment to `j`. So it is with strings in Icon.

Admittedly, there are operations in Icon that *appear* to change the characters in a string. For example,

```
s1[3] := "x"
```

gives the appearance of changing the third character in `s1` to "x". However, this expression is simply shorthand for

```
s1 := s1[1:3] || "x" || s1[4:0]
```

A new string is created by concatenation and a new qualifier for it is assigned to `s1`, as shown by

Of course, the length of the string may be increased or decreased by assignment to a substring, as in

```
s1[3] := "xxx"
s1 [2:5] := ""
```

### 5.1.4 Assignment to Subscripted Strings

Expressions such as `x[i]` and `x[i:j]` represent a particular challenge in the implementation of Icon. In the first place, the translator cannot determine the type of `x`. In the case of `x[i]`, there are four basic types that `x` may legitimately have: string, list, table, and record. Of course, any type that can be converted to a string is legitimate also. Unfortunately, the *nature* of the operation, not just the details of its implementation, depends on the type. For strings,

```
s1 [3] := s2
```

replaces the third character of `s1` by `s2` and is equivalent to concatenation, as described previously. For lists, tables, and records,

```
x[3] := y
```

changes the third *element* of `x` to `y` — quite a different matter (see Exercise 5.5).

This problem is pervasive in Icon and only needs to be noted in passing here. The more serious problem is that even if the subscripted variable is a string, the subscripting expression has different meanings, depending on the context in which it appears.

If `s` is a variable, then `s[i]` and `s[i:j]` also are variables. In a dereferencing context, such as

```
write(s[2:5])
```

the result produced by `s[2:5]` is simply a substring of `s`, and the subscripting expression produces the appropriate qualifier.

Assignment to a subscripted string, as in

```
s[2:5] := "xxx"
```

is not at all what it appears to be superficially. Instead, as already noted, it shorthand for an assignment to s:

`s := s[1] || "xxx" || s[6:0]`

If the translator could determine whether a subscripting expression is used in dereferencing or assignment context, it could produce different code for the two cases. As mentioned in Sec. 4.3.2, however, the translator cannot always make this determination. Consequently, trapped variables are used for subscripted strings much in the way they were used for keywords in Icon Version 6. For example, if the value of s is "abcdef", the result of evaluating the subscripting expression s[2:5] is a *substring trapped variable* that has the form

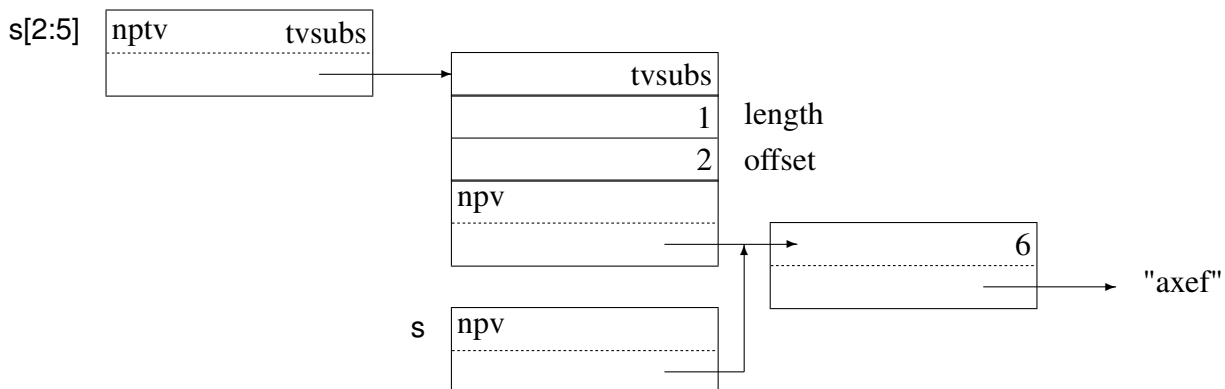

Note that both the variable for s and the variable in the substring trapped-variable block point to the same value. This makes it possible for assignment to the substring trapped variable to change the value of s.

The length and offset of the substring provide the necessary information either to produce a qualifier for the substring, in case the subscripting expression is dereferenced, or to construct a new string in case an assignment is made to the subscripting expression. For example, after an assignment such as

`s[2:5] := "x"`

the situation is

Note that the value of `s` has changed. The length of the subscripted portion of the string has been changed to correspond to the length of the string assigned to it. This reflects the fact that subscripting identifies the portions of the string before and after the subscripted portion ("a" and "ef", in this case). In the case of a multiple assignment to a subscripted string, only the original subscripted portion is changed. Thus, in

```
(s[2:5] := "x") := "yyyyy"
```

the final value of `s` is "ayyyyef".

### 5.1.5 Mapping

String mapping is interesting in its own right, and the RTL function that implements it illustrates several aspects of string processing:

```
function{1} map(s1,s2,s3)
/*
 * s1 must be a string; s2 and s3 default to (string
 * conversions of) &ucase and &lcase, respectively.
 */
if !cnv:string(s1) then
    runerr(103,s1)
...
abstract {
    return string
}
body {
    register int i;
    register word slen;
    register char *str1, *str2, *str3;
#ifdef Concurrent
    static char maptab[256];
#endif
    /* Concurrent */
    CURTSTATE();

    /*
     * Default is here, conversion only if cached maptab fails
     */
    if (is:null(s2))
        s2 = ucase;
    /*
```

```

    * Short-cut conversions of &lcase and &ucase.
    */
else {
    struct descrip _k_lcase_, _k_ucase_;
    Klcase(&_k_lcase_);
    Kucase(&_k_ucase_);
    if (s2.dword == D_Cset) {
        if (BlkLoc(s2) == BlkLoc(_k_lcase_)) {
            s2 = lcase;
        }
        else if (BlkLoc(s2) == BlkLoc(_k_ucase_)) {
            s2 = ucase;
        }
    }
}

if (is:null(s3))
    s3 = lcase;
/*
    * Short-cut conversions of &lcase and &ucase.
    */
else {
    struct descrip _k_lcase_, _k_ucase_;
    Klcase(&_k_lcase_);
    Kucase(&_k_ucase_);
    if (s3.dword == D_Cset) {
        if (BlkLoc(s3) == BlkLoc(_k_lcase_)) {
            s3 = lcase;
        }
        else if (BlkLoc(s3) == BlkLoc(_k_ucase_)) {
            s3 = ucase;
        }
    }
}

/*
    * If s2 and s3 are the same as for the last call of map,
    * the current values in maptab can be used. Otherwise, the
    * mapping information must be recomputed.

```

```

    */
    if (!EqIDesc(maps2,s2) || !EqIDesc(maps3,s3)) {
        maps2 = s2;
        maps3 = s3;
    }

    #if !COMPILE
        if (!cnv:string(s2,s2))
            runerr(103,s2);
        if (!cnv:string(s3,s3))
            runerr(103,s3);
    #endif
    /* !COMPILE */
    /*
    * s2 and s3 must be of the same length
    */
    if (StrLen(s2) != StrLen(s3))
        runerr(208);

    /*
    * The array maptab is used to perform the mapping. First,
    * maptab[i] is initialized with i for i from 0 to 255.
    * Then, for each character in s2, the position in maptab
    * corresponding to the value of the character is assigned
    * the value of the character in s3 that is in the same
    * position as the character from s2.
    */
    str2 = StrLoc(s2);
    str3 = StrLoc(s3);
    for (i = 0; i <= 255; i++)
        maptab[i] = i;
    for (slen = 0; slen < StrLen(s2); slen++)
        maptab[str2[slen]&0377] = str3[slen];
    }

    slen = StrLen(s1);

    if (slen == 0) {
        return emptystr;
    }
    else if (slen == 1) {

```

```

        char c = maptab[*StrLoc(s1) & 0xFF];
        return string(1, (char *)&allchars[FromAscii(c) & 0xFF]);
    }

    /*
     * The result is a string the size of s1; create the result
     * string, but specify no value for it.
     */
    StrLen(result) = slen;
    Protect(StrLoc(result) = alcstr(NULL, slen), runerr(0));
    str1 = StrLoc(s1);
    str2 = StrLoc(result);

    /*
     * Run through the string, using values in maptab to do the
     * mapping.
     */
    while (slen-- > 0)
        *str2++ = maptab[*str1++&0377];

    return result;
}
end

```

The mapping is done using the character array `maptab`. This array is set up by first assigning every possible character to its own position in `maptab` and then replacing the characters at positions corresponding to characters in `s2` by the corresponding characters in `s3`. Note that if a character occurs more than once in `s2`, its last (rightmost) correspondence with a character in `s3` applies.

To avoid rebuilding `maptab` unnecessarily, this step is bypassed if `map()` is called with the same values of `s2` and `s3` as in the previous call. The global (in [Unicon](#), [thread-local](#)) variables `maps2` and `maps3` are used to hold these "cached" values. The macro `EqIDesc(d1,d2)` tests the equivalence of the descriptors `d1` and `d2`.

The function `map()` is an example of a function that defaults null-valued arguments. Omitted arguments are supplied as null values. The defaults for `s2` and `s3` are `&ucase` and `&lcase`, respectively. Consequently,

```

    map(s)

```

is equivalent to

```

    map(s, &ucase, &lcase)

```

The macro `ChkNull(d)` tests whether or not `d` is null. The values of `&ucase` and `&lcase` are in the global constants `ucase` and `lcase`.

## 5.2 Csets

Since Icon uses 8-bit characters, regardless of the computer on which it is implemented, there are 256 different characters that can occur in csets. A cset block consists of the usual title containing the cset type code followed by a word that contains the number of characters in the cset. Next, there are words containing a total of 256 bits. Each bit represents one character, with a bit value of 1 indicating that the character is present in the cset and a bit value of 0 indicating it is absent. An example is the value of the keyword `&ascii`:

The first 128 bits are 1, since these are the bits that correspond to those in ASCII character set. The C structure for a cset block is

```
struct b_cset {                /* cset block */
    word title;                /* T_Cset */
    word size;                 /* size of cset */
    unsigned int bits [CsetSize]; /* array of bits */
};
```

where `CsetSize` is the number of words required to make up a total of 256 bits. `CsetSize` is 8 on a computer with 32-bit words and 4 on a computer with 64-bit words. Few programs use the size of Csets and the calculation of the size is expensive. The size field is set initially to -1 (by the routine `alccset()`) and the actual size is only computed if it is needed subsequently.

Cset operations are comparatively straightforward. The characters in a cset are represented by a bit vector that is divided into words to accommodate conventional computer architectures. For example, the C code for cset complementation is

```
operator{1} ~ compl(x)
/*
 * x must be a cset.
```

```

    */
    if !cnv:tmp_cset(x) then
        runerr(104, x)

    abstract {
        return cset
    }
    body {
        register int i;
        struct b_cset *cp, *cpx;

        /*
         * Allocate a new cset and then copy each cset word from
         * x into the new cset words, complementing each bit.
         */
        Protect(cp = alccset(), runerr(0));
        /* must come after alccset() since BlkLoc(x) could move */
        cpx = (struct b_cset *)BlkLoc(x);
        for (i = 0; i < CsetSize; i++)
            cp->bits[i] = ~cpx->bits[i];
        return cset(cp);
    }
end

```

RETROSPECTIVE: The central role of strings in Icon and the nature of the operations performed on them leads to a representation of string data that is distinct from other data. The qualifier representation is particularly important in providing direct access to string length and in allowing the construction of substrings without the allocation of additional storage. The penalty paid is that a separate test must be performed to distinguish strings from all other kinds of values.

The ability to assign to subscripted strings causes serious implementation problems. The trapped-variable mechanism provides a solution, but it does so at considerable expense in the complexity of code in the run-time system as well as storage allocation for trapped-variable blocks. This expense is incurred even if assignment is not made to a subscripted string.

## EXERCISES

**5.1** What are the ramifications of Icon's use of the 256-bit ASCII character set, regardless of the "native" character set of the computer on which Icon is implemented?

**5.2** Catalog all the operations on strings in Icon and point out any that might cause special implementation problems. Indicate the aspects of strings and string operations in Icon that are the most important in terms of memory requirements and processing speed.

**5.3** List all the operations in Icon that require the allocation of space for the construction of strings.

**5.4** It has been suggested that it would be worth trying to avoid duplicate allocation of the same string by searching the string region for a newly created string to see if it already exists before allocating the space for it. Evaluate this proposal.

**5.5** Consider the following four expressions:

```
s1 [i] := s2
s1 [i+:1] := s2
a1 [i] := a2
a1 [i+:1] := a2
```

where *s1* and *s2* have string values and *a1* and *a2* have list values. Describe the essential differences between the string and list cases. Explain why these differences indicate flaws in language design. Suggest an alternative.

**5.6** The substring trapped-variable concept has the advantage of making it possible to handle all the contexts in which string-subscripting expressions can occur. It is expensive, however, in terms of storage utilization. Analyze the impact of this feature on the performance of “typical” Icon programs.

**5.7** Since the contexts in which most subscripting expressions occur can be determined, describe how to handle these without using trapped variables.

**5.8** If a subscripting expression is applied to a result that is not a variable, it is erroneous to use such an expression in an assignment context. In what situations can the translator detect this error? Are there any situations in which a subscripting expression is applied to a variable but in which the expression cannot be used in an assignment context?

**5.9** There are some potential advantages to unifying the keyword and substring trapped-variable mechanisms into a single mechanism in which all trapped variables would have pointers to functions for dereferencing and assignment. What are the disadvantages of such a unification?

**5.10** Presumably, it is unlikely for a programmer to have a constructive need for the polymorphic aspect of subscripting expressions. Or is it? If it is unlikely, provide a supporting argument. On the other hand, if there are situations in which this capability is useful, describe them and give examples.

**5.11** In some uses of `map(s1, s2, s3)`, *s1* and *s2* remain fixed while *s3* varies (Griswold 1980b). Devise a heuristic that takes advantage of such usage.

# Chapter 6

## Lists

**PERSPECTIVE:**Most programming languages support some form of vector or array data type in which elements can be referenced by position. Icon's list data type fills this need, but it differs from similar types in many languages in that Icon lists are constructed during program execution instead of being declared during compilation. Therefore, the size of a list may not be known until run time.

Icon's lists are data objects. They can be assigned to variables and passed as arguments to functions. They are not copied when this is done; in fact, a value of type list is simply a descriptor that points to the structure that contains the list elements. These aspects of lists are shared by several other Icon data types and do not add anything new to the implementation. The attribute of lists that presents the most challenging implementation problem is their ability to grow and shrink by the use of stack and queue access mechanisms.

Lists present different faces to the programmer, depending on how they are used. They may be static vectors referenced by position or they may be dynamic changing stacks or queues. It might seem that having a data structure with such apparently discordant access mechanisms would be awkward and undesirable. In practice, Icon's lists provide a remarkably flexible mechanism for dealing with many common programming problems. The two ways of manipulating lists are rarely intermixed. When both aspects are needed, they usually are needed at different times. For example, the number of elements needed in a list often is not known when the list is created. Such a list can be created with no elements, and the elements can be pushed onto it as they are produced. Once such a list has been constructed, it may be accessed by position with no further change in its size.

### 6.1 Structures for Lists

The fusion of vector, stack, and queue organizations is reflected in the implementation of Icon by relatively complicated structures that are designed to provide a reasonable compromise between the conflicting requirements of the different access mechanisms.

A list consists of a fixed-size *list-header block*, which contains the usual title, the current size

of the list (the number of elements in it), and block pointers that point to the first and last blocks on a doubly-linked chain of *list-element blocks* that contain the actual list elements. List-element blocks vary in size.

A list-element block contains the usual title, the size of the block in bytes, three words used to determine the locations of elements in the list-element block and block pointers that point to the next and previous list-element blocks, if any. A null pointer ([in Unicon, a pointer back to the list header block](#)) indicates the absence of a pointer to another list-element block. Following this data, there are slots for elements. Slots always contain valid descriptors, even if they are not used to hold list elements.

The structure declarations for list-header blocks and list-element blocks are

```
struct b_list {          /* list-header block */
    word title;          /* T_List */
    word size;           /* current list size */
    word id;             /* identification number */
    union block *listhead; /* first list-element block */
    union block *listtail; /* last list-element block */
};

struct b_lelem {         /* list-element block */
    word title;          /* T_Lelem */
    word blksize;        /* size of block */
    word nslots;         /* total number of slots */
    word first;          /* index of first used slot */
    word nused;          /* number of used slots */
    union block *listprev; /* previous list-element block */
    union block *listnext; /* next list-element block */
    struct descrip lslots[1]; /* array of slots */
};
```

When a list is created, either by

list(n, x)

or by

[x1 ,x2, ..., xn]

there is only one list-element block. Other list-element blocks may be added to the chain as the result of pushes or puts.

List-element blocks have a minimum number of slots. This allows some expansion room for adding elements to lists, such as the empty list, that are small initially. The minimum number of slots is given by `MinListSlots`, which normally is eight. In the examples that follow, the value of `MinListSlots` is assumed to be four in order to keep the diagrams to a manageable size.

The code for the list function is

```

function{1} list(n, x)
  if is:set(n) then {
    abstract {
      return new list(store[type(n).set_elem])
    }
    body {
      struct descrip d;
      cnv_list(&n, &d); /* can't fail, we know n is a set */
      return d;
    }
  }
  else {
    if !def:C_integer(n, 0L) then
      runerr(101, n)

    abstract {
      return new list(type(x))
    }

    tended struct b_list *hp;
    register word i, size;
    word nslots;
    register struct b_lelem *bp; /* doesnt need to be tended */

    nslots = size = n;

    /*
     * Ensure that the size is positive and that the
     * list-element block has at least MinListSlots slots.
     */
    if (size < 0) {
      irunerr(205, n);
      errorfail;
    }
    if (nslots == 0)
      nslots = MinListSlots;
    /*
     * Allocate the list-header block and a list-element block.
     * nslots is the number of slots in the list-element

```

```

    * block while size is the number of elements in the list.
    */
    Protect(hp = alclist_raw(size, nslots), runerr(0));
    bp = (struct b_lelem *)hp->listhead;

    /*
    * Initialize each slot.
    */
    for (i = 0; i < size; i++)
        bp->lslots[i] = x;

    Desc_EVValD(hp, E_Lcreate, D_List);

    /*
    * Return the new list.
    */
    return list(hp);
}
}
end

```

The data structures produced for a list are illustrated by the result of evaluating

```
a := list(1, 4)
```

which produces a one-element list containing the value 4:

Data Structures for list(1,4)

Note that there is only one list-element block and that the slot indexing in the block is zero-based. Unused slots contain null values that are logically inaccessible.

## 6.2 Queue and Stack Access

Elements in a list-element block are stored as a doubly-linked circular queue. If an element is added to the end of the list *a*, as in

```
put(a, 5)
```

the elements of the list are 4 and 5. The value is added to the "end" of the last list-element block, assuming there is an unused slot (as there is in this case). The code in `put()` to do this is

```
/*
 * Point hp to the list-header block and bp to the last
 * list-element block.
```

```

    */
    hp = (struct b_list *)BlkLoc(x);
    bp = (struct b_lelem *) hp->listtail;
    /*
     * If the last list-element block is full, allocate a new
     * list-element block, make it the first list-element block,
     * and make it the next block of the former last list-element
     * block.
     */
    if (bp->nused >= bp->nslots) {
        /*
         * Set i to the size of block to allocate.
         */
        i = hp->size / two;
        if (i < MinListSlots)
            i = MinListSlots;
#ifdef MaxListSlots
        if (i > MaxListSlots)
            i = MaxListSlots;
#endif
        /* MaxListSlots */
        /*
         * Allocate a new list element block. If the block
         * can't be allocated, try smaller blocks.
         */
        while ((bp = alclstb(i, (word)0, (word)0)) == NULL) {
            i /= 4;
            if (i < MinListSlots)
                runerr(0);
        }

        hp->listtail->lelem.listnext = (union block *) bp;
        bp->listprev = hp->listtail;
        hp->listtail = (union block *) bp;
    }
    /*
     * Set i to position of new last element and assign val to
     * that element.
     */
    i = bp->first + bp->nused;

```

```

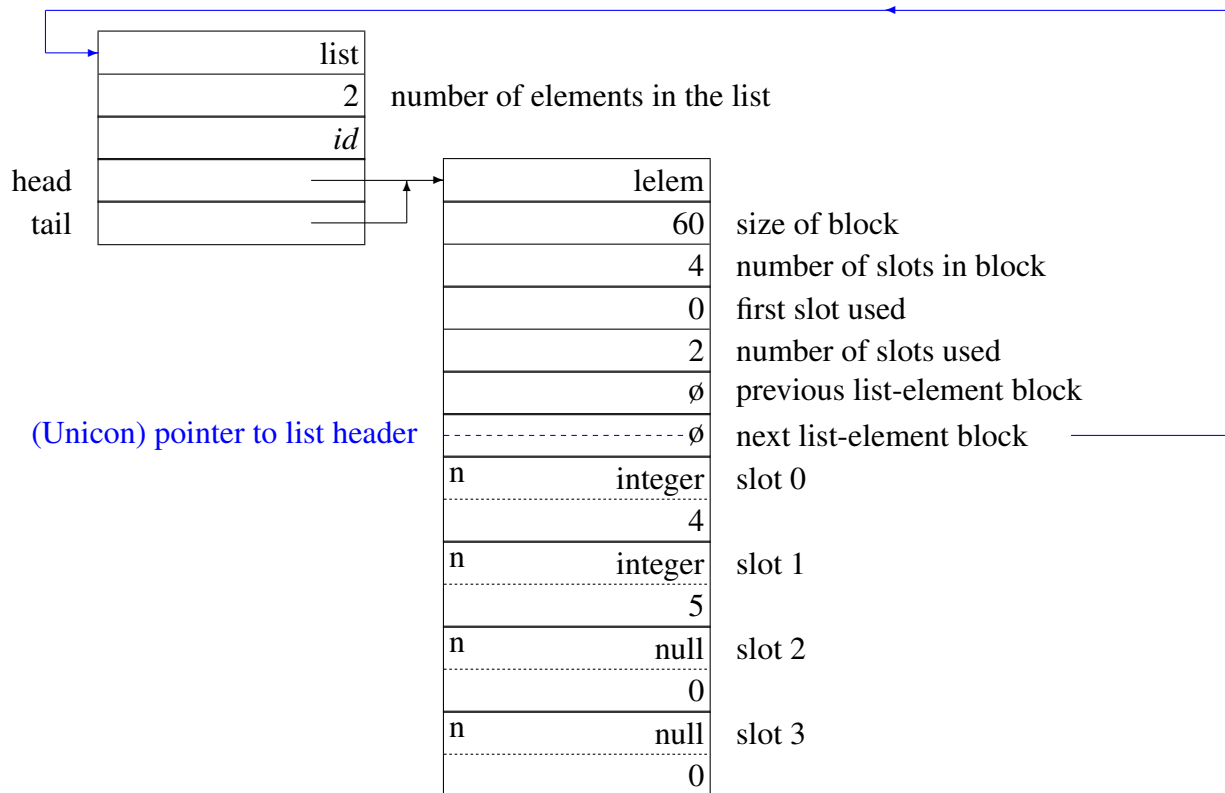

if (i >= bp->nslots)
    i -= bp->nslots;
bp->lslots[i] = dp[val];

/*
 * Adjust block usage count and current list size.
 */
bp->nused++;
hp->size++;
}

/*
 * Return the list.
 */
return x;
}
end

```

The effect on the list-header block and list-element block is:

The List Element-Block after a put

Note that the increase in the number of elements in the header block and in the number of slots used in the list-element block.

If an element is added to the beginning of a list, as in

`push(a,3)`

the elements of the list are 3, 4, and 5. The new element is put at the "beginning" of the first list-element block. The result is

#### The List Element-Block after a push

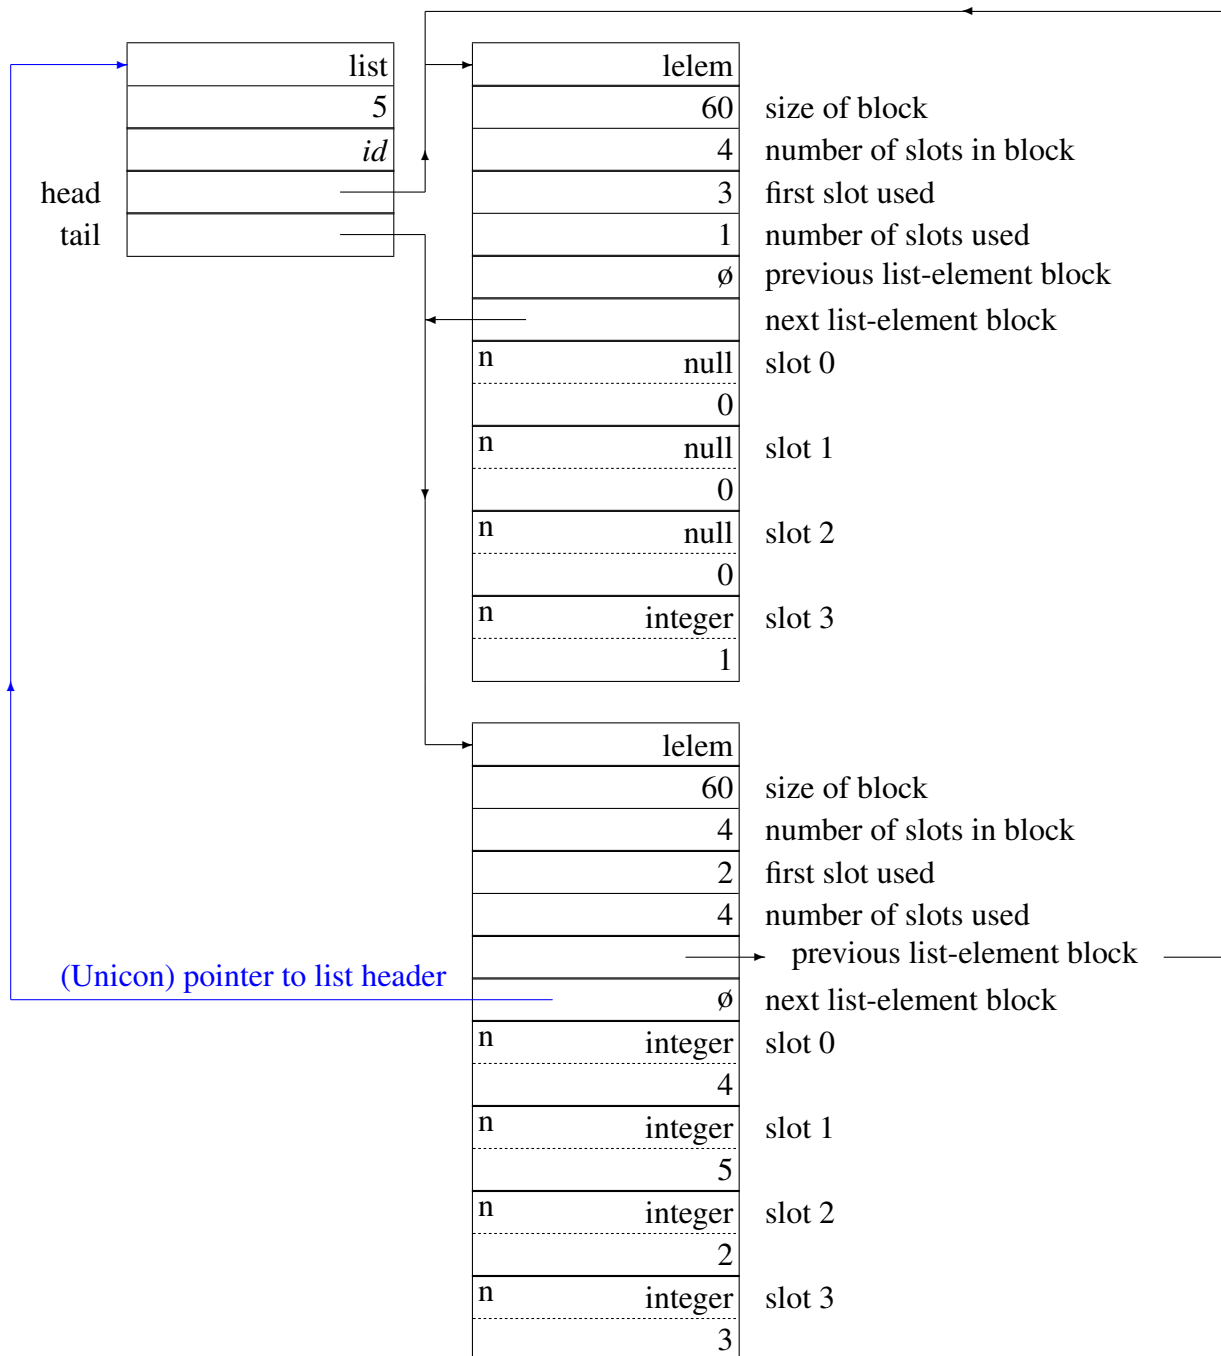

Note that the "beginning," which is before the first physical slot in the list-element block, is the last physical slot. The locations of elements that are in a list-element block are determined by the three integers at the head of the list element block. "Removal" of an element by a pop, get, or pull does not shorten the list-element block or overwrite the element; the element merely becomes inaccessible.

If an element is added to a list and no more slots are available in the appropriate list-element block, a new list-element block is allocated and linked in. The size of the new block is half the number of elements in the entire list before expansion or `MinListSlots`, whichever is greater. **Unicon also imposes an upper limit of `MaxListSlots` on the size of the new block.** However, if there is not enough memory to allocate a list-element block of the desired size, the size is reduced to fit into available memory. For example, following evaluation of

`push(a,2)`

push(a,1)

the list elements are 1,2,3,4, and 5. The resulting structures are

### The Addition of a List-Element Block

As elements are removed from a list by `pop` (which is synonymous with `get`) or `pull`. The indices in the appropriate list-element block are adjusted. The code for `pop` is

```

int c_get(hp, res)
struct b_list *hp;
struct descrip *res;
{
    register word i;
    register struct b_lelem *bp;

    /*
     * Fail if the list is empty.
     */
    if (hp->size <= 0)
        return 0;

    /*
     * Point bp at the first list block.  If the first block has
     * no elements in use, point bp at the next list block.
     */
    bp = (struct b_lelem *) hp->listhead;
    if (bp->nused <= 0) {
        bp = (struct b_lelem *) bp->listnext;
        hp->listhead = (union block *) bp;
        bp->listprev = NULL;
    }

    /*
     * Locate first element and assign it to result for return.
     */
    i = bp->first;
    *res = bp->slots[i];

    /*
     * Set bp->first to new first element, or 0 if the block is
     * now empty.  Decrement the usage count for the block and
     * the size of the list.
     */
    if (++i >= bp->nslots)
        i = 0;
    bp->first = i;
    bp->nused--;
}

```

```

    hp->size--;
    return 1;
}

```

where the `c_get()` helper function is invoked from RTL as follows:

```

function{0,1} get_or_pop(x)
  if !is:list(x) then
    runerr(108, x)

    abstract {
      return store[type(x).lst_elem]
    }

    body {
      if (!c_get((struct b_list *)BlkLoc(x), &result)) fail;
      return result;
    }
end

```

Thus, as a result of

```
pop(a)
```

the list elements are 2, 3, 4, and 5. The resulting structures are

### The Result of Removing Elements from a List-Element Block

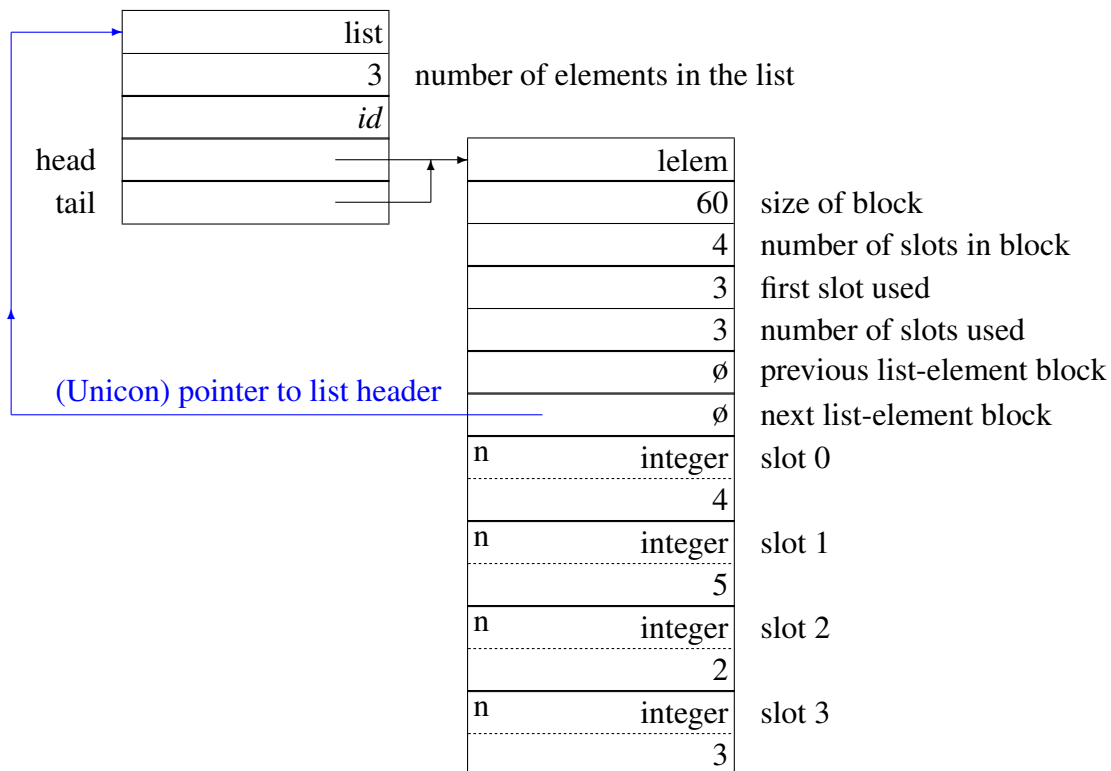

Note that the first list-element block is still linked in the chain, even though it no longer contains any elements that are logically accessible. A list-element block is not removed from the chain when it becomes empty. It is removed only when an element is removed from a list that already has an empty list-element block. Thus, there is always at least one list-element block on the chain, even if the list is empty. Aside from simplifying the access to list-element blocks from the list-header

block, this strategy avoids repeated allocation in the case that pop/push pairs occur at the boundary of two list-element blocks.

Continuing the previous example,

`pop(a)`

leaves the list elements 3, 4, and 5. The empty list-element block is removed from the chain:

#### Removal of an Empty List-Element Block

Note that the value 2 is still physically in the list-element block, although it is logically inaccessible.

## 6.3 Positional Access

Positional reference of the form `a[i]` requires locating the correct list-element block. Out-of-range references can be determined by examining the list-header block. If the list has several list-element blocks, this involves linking through the list-element blocks, while keeping track of the count of elements in each block until the appropriate one is reached. The result of evaluating `a[i]` is a variable that points to the appropriate slot.

The portion of the subscripting code that handles lists is

```

type_case dx of {
  list: {
    abstract {
      return type(dx).lst_elem
    }
    /*
     * Make sure that y is a C integer.
     */
    if !cnv:C_integer(y) then {
      /*
       * If it isn't a C integer, but is a large integer,
       * fail on the out-of-range index.
       */
      if cnv : integer(y) then inline { fail; }
      runerr(101, y)
    }
    body {
      word i, j;
      register union block *bp; /* no need to be tended */
      struct b_list *lp; /* doesn't need to be tended */

      /*
       * Make sure that subscript y is in range.
       */
      lp = (struct b_list *)BlkLoc(dx);
      i = cvpos((long)y, (long)lp->size);
      if (i == CvtFail || i > lp->size)
        fail;
      /*
       * Locate the list-element block containing the
       * desired element.
       */
      bp = lp->listhead;
      j = 1;
      /*
       * y is in range, so bp can never be null here. If it
       * was, a memory violation would occur in the code that
       * follows, anyhow, so exiting the loop on a NULL bp
       * makes no sense.

```

```

    */
while (i >= j + bp->lelem.nused) {
    j += bp->lelem.nused;
    bp = BlkLoc(bp->lelem.listnext);
}

/*
 * Locate desired element and return a pointer to it.
 */
i += bp->lelem.first - j;
if (i >= bp->lelem.nslots)
    i -= bp->lelem.nslots;
return struct_var(&bp->lelem.lslots[i], bp);
}
}

```

For the preceding example, `a[3]` produces a variable that points indirectly to the descriptor for the value 5:

### Referencing a List Element

Note the offset of nine words in the d-word of the variable. In version 6 of Icon the descriptor pointed directly at the variable and the offset enabled the garbage collector to locate the top of the block. In current versions of Icon and Unicon the variable points to the top of the block and the offset enables the correct list-element to be referenced. This change was necessitated by the introduction of block pointers — see Chapter 11 for details.

## 6.4 Arrays (Unicon only)

The Unicon language provides a special case of the general list structure that is optimized for fast access to the list-elements. An array is a list where all the list-elements are the same numeric type and are in a single block. It is created by calling

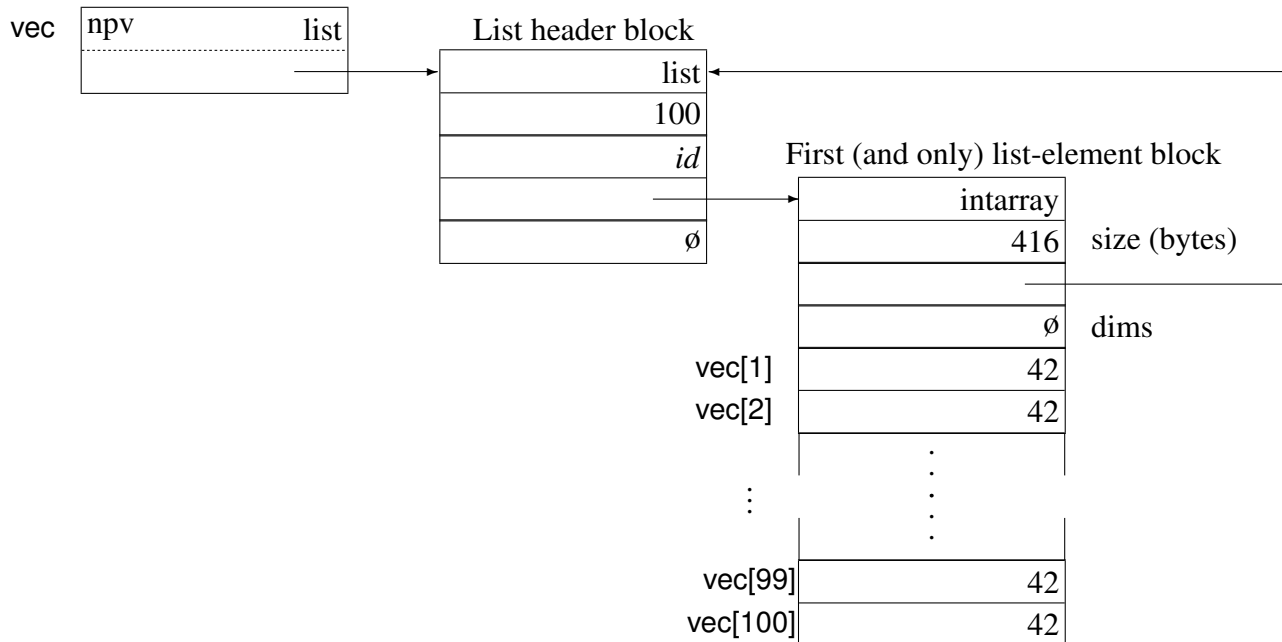

`array(dimen, value)`

which will return a one dimensional “vector” of *dimen* elements that are all set to *value*. *value* may be a small integer or a floating point value. It may also be a list, in which case the value for the array is the value of the first element of the list.

For example, following evaluation of

`vec := array(100,42)`

there will be 100 integers in the array, all set to 42. The resulting structures are

At present (January 2017) multi-dimensional arrays are not supported, although there is provision in the data structures for more than one dimension. Multi dimensional arrays will be created by calling

`array(dimen1, dimen2, ..., dimenn, value)`

The only change to the diagram above will be that the null pointer in the `dims` field will be replaced by a pointer to another `intarray` block that contains each of the values *dimen*<sub>1</sub> ... *dimen*<sub>n</sub>.

Provided that the elements in the array are only assigned values of the same initial type, they will stay together in one contiguous block and enjoy the benefits of faster access. If a value of a different type is assigned or an array element is deleted, or the array is extended (by push or put) the runtime system converts the array into a conventional list. The code extract to convert an integer array to a list (taken from the `asgn` operator) is below. In the extract, *x* is a descriptor that points to the array element and *y* is a descriptor that points to the new value.

```

if (BlkD(x,Intarray)->title==T_Intarray){
    C_integer ii;
    if (cnv:(exact)C_integer(y, ii))
        *((word *)VarLoc(x) + Offset(x)) = ii;
    else{ /* y is not integer, try to convert the intarray to list*/
        tended struct b_list *xlist= BlkD(x, Intarray)->listp;
        tended struct descrip dlist;
        word i;

        i = (Offset(x)*sizeof(word)-sizeof(struct b_intarray)+
            sizeof(word)) / sizeof(word);

        dlist.vword.bptr = (union block *) xlist;
        dlist.dword = D_List;
        if (arraytolist(&dlist)!=Succeeded) fail;

        /*
         * assuming the new list has one lelem block only,
         * i should be in the first block. no need to loop
         * through several blocks
         */

        *(dptr)(&xlist->listhead->Lelem.lslots[i]) = y;
    }
}

```

The code to convert an array of real values is very similar to the code for integer arrays.

**RETROSPECTIVE:** The structures used for implementing lists are relatively complicated, but they provide a reasonable compromise, both in the utilization of storage and access speed, that accommodates different access mechanisms.

Using a chain of list-element blocks allows lists to grow in size without limit. From the view-point of positional access, this amounts to segmentation. This segmentation only occurs, however, when elements are added to a list. The use of circular queues within list-element blocks allows elements to be removed and added without wasting space.

Arrays provide a useful speed-up in cases where the list elements are numeric and the list does not grow or shrink.

## EXERCISES

1. 1.1 Diagram the structures that result from the evaluation of the following expressions:
 

```
graph := ["a",,]
graph[2] := graph[3] := graph
```
- 1.2 How much space does an empty list occupy?
- 1.3 The portions of the structures for a list that are not occupied by elements of the list constitute overhead. Calculate the percentage of overhead in the following lists. Assume that the minimum number of slots in a list-element block is eight.
 

```
a := []
a := [1, 2]
a := [1, 2, 3, 4, 5]
a := list(100)
a := []; every put(a, 1 to 100)
```

 How do these figures vary as a function of the minimum number of slots in a list-element block?
- 1.4 What are the implications of not “zeroing” list elements when they are logically removed by a pop, get, or pull?
- 1.5 When a list-element block is unlinked as the result of a pop, get, or pull, are the elements in it really inaccessible to the source program?
- 1.6 There is considerable overhead involved in the implementation of *lists* to support both positional access and stack and queue access mechanisms. Suppose the language were changed so that stack and queue access mechanisms applied only to lists that were initially empty. What would the likely impact be on existing Icon programs? How could the implementation take advantage of this change?
- 1.7 As elements are added to lists, more list-element blocks are added and they tend to become “fragmented.” Is it feasible to reorganize such lists, combining the elements in many list-element blocks into one large block? If when and how could this be done?
- 1.8 A suggested alternative to maintaining a chain of list-element blocks is to allocate a larger block when space is needed and copy elements from the previous block into it. Criticize this proposal.
- 1.9 Suppose it were possible to insert elements in the middle of lists, rather than only at the ends. How might this feature be implemented?

# Chapter 7

## Sets and Tables

PERSPECTIVE: Sets and tables are data aggregates that are very useful for a number of common programming tasks. Nevertheless, few programming languages support these data types, with the notable exceptions of Sail (Reiser 1976) and SETL (Dewar, Schonberg, and Schwartz 1981). There are many reasons why these obviously useful data types are not found in most programming languages, but perceived implementation problems certainly rank high among them. If only for this reason, their implementation in Icon is worth studying.

Historically, tables in Icon were inherited from SNOBOL4 and SL5. Sets came later, as an extension to Icon, and were designed and implemented as a class project. Although sets were a late addition to Icon, they are simpler than tables. Nonetheless, they present many of the same implementation problems that tables do. Consequently, sets are considered here first.

Sets and the operations on them support the familiar mathematical concepts of finite sets: membership, the insertion and deletion of members, and the operations of union, intersection, and difference. What is interesting about a set in Icon is that it can contain members of any data type. This is certainly a case where heterogeneity significantly increases the usefulness of a data aggregate without adding to the difficulty of the implementation, *per se*.

The ability of a set to grow and shrink in size influences the implementation significantly. Efficient access to members of a set, which is needed for testing membership as well as the addition and deletion of members, is an important consideration, since sets can be arbitrarily large.

Tables have more structure than sets. Abstractly, a table is a set of pairs that represents a many-to-one relationship—a function. In this sense, the default value of a table provides an extension of the partial function represented by the entry and assigned value pairs to a complete function over all possible entry values. Programmers, however, tend to view tables in a more restricted way, using them to tabulate the attributes of a set of values of interest. In fact, before sets were added to Icon, tables were often used to simulate sets by associating a specific assigned value with membership.

## 7.1 Sets

### 7.1.1 Data Organization for Sets

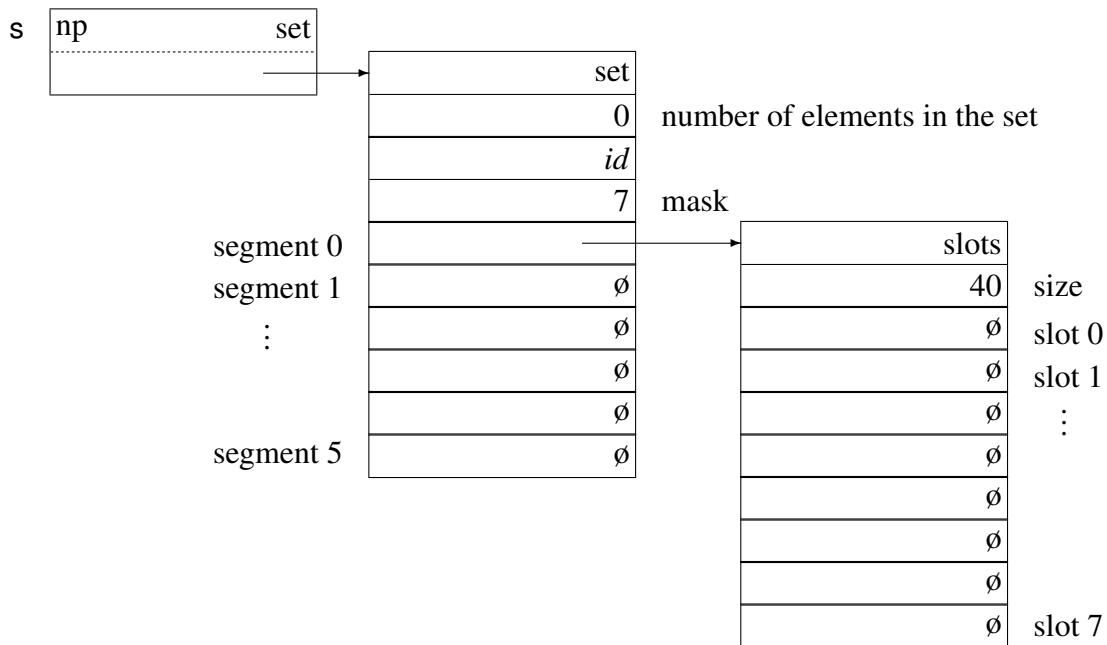

Hash lookup and linked lists are used to provide an efficient way of locating set members. For every set there is a set-header block that contains a word for the number of members in the set and slots that serve as heads for (possibly empty) linked lists of set-element blocks. The number of slots is an implementation parameter. In version 6 of Icon there were thirty-seven slots in table-header blocks on computers with large address spaces but only thirteen slots on computers with small address spaces. This worked well for small hash tables, but performance degraded for large tables due to the long hash chains in each slot.

Now, the hash table is segmented; each hash table starts out with a single segment containing a fixed number of slots (typically eight), but the number of slots doubles repeatedly as the number of segments grows. Small hash tables benefit from reduced memory requirements, while large tables show dramatic performance gains. The price paid is one extra indirection to get to the lists of members. The maximum number of segments in a set header block is a configuration parameter: The default is six on machines with small address spaces and ten otherwise. [Unicon allows up to twenty segments, which places an upper limit on the maximum possible number of slots \(albeit quite a large one of  \$slots \times 2^{19}\$ \).](#) To reduce the size of the diagrams the maximum number of segments is assumed to be six in the figures that follow but, even with this low number, the maximum number of slots is 256 ( $8 + 8 + 16 + 32 + 64 + 128$ ), which is still a respectable increase compared to version 6.

The structure for an empty set, produced by

```
s := set()
```

is

Each member of a set is contained in a separate set-element block. When a value is looked up in a set (for example, to add a new member), a hash number is computed from this value. The absolute value of the remainder resulting from dividing the hash number by the number of slots is used to select a slot.

Each set-element block contains a descriptor for its value, the corresponding hash number, and a pointer to the next set-element block, if any, on the linked list. For example, the set-element block for the integer 10 is:

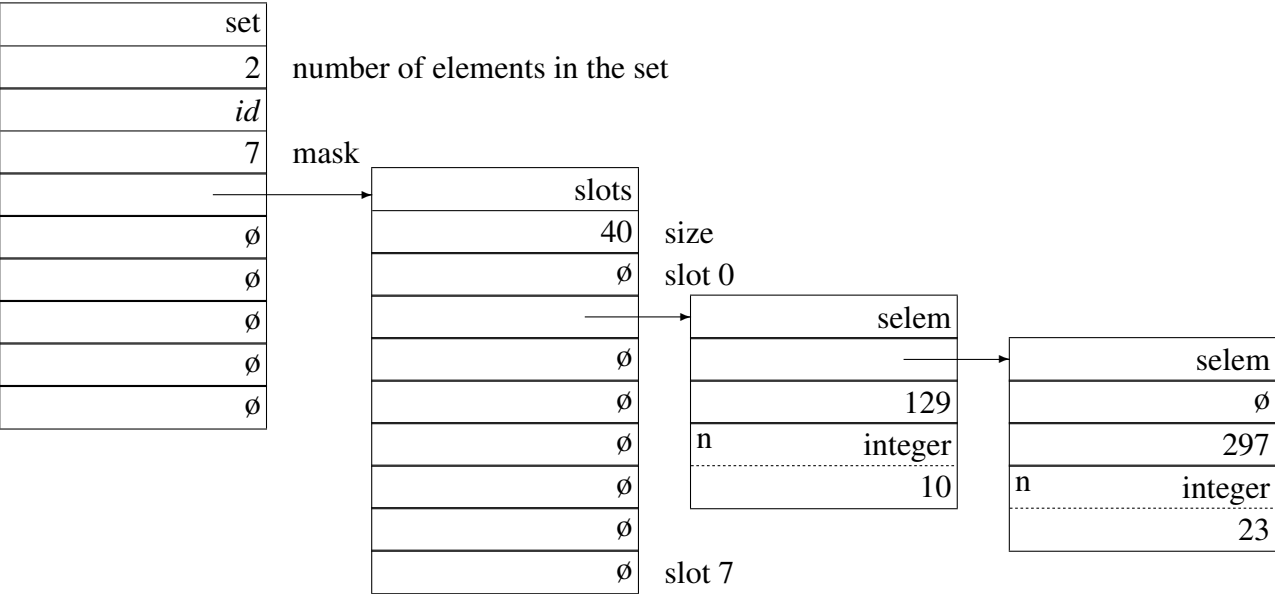

As illustrated by this figure, the hash number for an integer is not the value of the integer (in Icon Version 6 it was). The hash number for an integer is the result of multiplying it by eight times the golden ratio using fixed point arithmetic. Hash computation is discussed in detail in Sec. 7.3.

The structures for the set

```
s := set([10,23])
```

are

This example was chosen for illustration, since both 10 and 23 go in slot 1.

In searching the list, the hash number of the value being looked up is compared with the hash numbers in the set-element blocks. If a match is found, the value in the set-element block may or may not be the same as the value being looked up, since collisions in the hash computation are unavoidable. Thus, if the hash numbers are the same, it is necessary to determine whether or not their values are equivalent. The comparison that is used is the same one that is used by the source-language operation `x === y`.

To improve the performance of the lookup process, the set-element blocks in each linked list are ordered by their hash numbers. When a linked list of set-element blocks is examined, the search stops if a hash number of an element on the list is greater than the hash number of the value being looked up.

If the value is not found and the lookup is being performed to insert a new member, a set-element block for the new member is created and linked into the list at that point. For example,

```
insert(s, 2)
```

inserts a set-element block for 2 at the head of the list in slot 1, since its hash value is 25. The word in the set-header block that contains the number of members is incremented to reflect the insertion.

7.1.2 Set Operations

The set operations of union, intersection, and difference all produce new sets and do not modify their arguments.

In the case of union, a copy of the larger set is made first to provide the basis for the union. This involves not only copying the set-header block but also all of its set-element blocks. These

are linked together as in the original set, and no lookup is required. After this copy is made, each member of the set for the other argument is inserted in the copy, using the same technique that is used in insert. The larger set is copied, since copying does not require lookup and the possible comparison of values that insertion does. The insertion of a member from the second set may take longer, however, since the linked lists in the copy may be longer.

In the case of intersection, a copy of the smaller argument set is made, omitting any of its members that are not in the larger set. As with union, this strategy is designed to minimize the number of lookups.

For the difference of two sets, a copy of the first argument set is made, adding only elements that are not in the second argument. This involves looking up all members in the first argument set in the second argument set.

## 7.2 Tables

### 7.2.1 Data Organization for Tables

The implementation of tables is similar to the implementation of sets, with a header block containing slots for elements ordered by hash numbers. A table-header block contains an extra descriptor for the default assigned value.

An empty table with the default assigned value 0 is produced by

$t := \text{table}(0)$

The structure of the table-header is

Table lookup is more complicated than set lookup, since table elements contain both an entry value and an assigned value. Furthermore, table elements can be referenced by variables. A new table element is created as a byproduct of assignment to a table reference with an entry value that is not in the table.

The result of evaluating an assignment expression such as

`t[10] := 1`

illustrates the structure of a table-element block:

In the case of a table reference such as `t[x]`, the hash number for the entry value `x` is used to select a slot, and the corresponding list is searched for a table-element block that contains the same entry value. As in the case of sets, comparison is first made using hash numbers; values are compared only if their hash numbers are the same.

If a table-element block with a matching entry value is found, a variable that points to the corresponding assigned value is produced. For example, if 10 is in `t` as illustrated previously, `t[10]` produces

If this variable is dereferenced, as in

`write(t[10])`

the value 1 is written. On the other hand, if an assignment is made to this variable, as in

`t[10] += 1`

the assigned value in the table-element block is changed:

	telem	
	∅	next table-element block
	129	hash number
n	integer	entry value
	10	
n	integer	assigned value
	2	

If a table element with a matching entry value is not found, the situation is very similar to that in a subscripted string: the operation to be performed depends on whether the table reference is used in a dereferencing or assignment context. In a dereferencing context, the default value for the table is produced, while in an assignment context, a new element is added to the table.

The approach taken is similar to that for subscripted strings: a trapped variable is created. As with substring trapped variables, table-element trapped variables contain the information that is necessary to carry out the required computation for either dereferencing or assignment.

Suppose, for example, that the entry value 36 is not in the table *t*. Then *t*[36] produces the following result:

If this trapped variable is dereferenced, as in

`write(t[36])`

the default assigned value, 0, which is in the table-header block for *t*, is produced. Unfortunately, the situation is not always this simple. It is possible for elements to be inserted in a table between the time the table-element trapped-variable block is created and the time it is dereferenced. An example is

`write(t[36] , t[36] := 2)`

Since functions do not dereference their arguments until all the arguments have been evaluated, the result of dereferencing the first argument of `write` should be 2, not 0. In order to handle such cases, when a table-element trapped variable is dereferenced, its linked list in the table must be searched again to determine whether to return the assigned value of a newly inserted element or to return the default value.

If an assignment is made to the table reference, as in

`t[36] += 1`

the table-element trapped-variable block is copied to a new table-element block with the assigned value stored in the new block.

It then is necessary to search the linked list for its slot to determine the place to insert the table-element block. As in the case of dereferencing, elements may have been inserted in the table between the time the table-element trapped variable was created and the time a value is assigned to it. Normally, no matching entry is found, and the new table-element block, is inserted with the new assigned value. If a matching entry is found, its assigned value is simply changed, and the block is discarded.

Note that reference to a value that is not in a table requires only one computation of its hash value, but two lookups are required in the linked list of table-element blocks for its slot.

## 7.3 Hashing Functions

Ideally, a hash computation should produce a different result for every different value to which it is applied, and the distribution of the remainder on division by the number of slots should be uniform. Even approaching this ideal requires an impractical amount of computation and space. In practice, it is desirable to have a fast computation that produces few collisions.

The subject of hash computation has been studied extensively. In general, there is a trade-off between faster lookup, on the average, and more storage overhead. Beyond this, there is a substantial body of knowledge concerning useful techniques (Knuth 1973, pp. 506-549). For example, there are fewer collisions if the number of slots is a prime that is not close to a power of two. Originally, this consideration motivated the choices of 37 and 13 for number of hash table slots on computers with large and small address spaces, respectively. As computer memory sizes grew, the one-size-fits-all strategy was replaced with one that increases the number of slots as needed (Griswold and Townsend 1993).

In most situations in which hashing techniques are used, all the values for which hash computations are performed are strings. In Icon, however, any kind of value can be the member of a set or the entry value in a table. The hash computation must, therefore, apply to any type of value. The support routine for computing hash numbers first checks for a string, and then has a switch statement to handle all the other types.

The string hashing implementation is important and deserves extra scrutiny. The Unicon implementation differs from Icon and is shown in blue; the `#ifdef` is included for exposition and is not in the code.

```
uword hash(dp)
dptr dp;
{
    register char *s;
```

```

register uword i;
register word j, n;
register unsigned int *bitarr;
double r;
if (Qual(*dp)) {

```

```

#ifdef Unicon
hashstring:
/*
 * Compute the hash value for the string based on a scaled sum
 * of its first and last several characters, plus its length.
 * Loops are unrolled.
 */
i = 0;
s = StrLoc(*dp);
n = StrLen(*dp);

switch(n){
  case 20: i ^= (i << 7) ^ (*s++) ^ (i >> 3);
  case 19: i ^= (i << 11) ^ (*s++) ^ (i >> 5);
  case 18: i ^= (i << 7) ^ (*s++) ^ (i >> 3);
  case 17: i ^= (i << 11) ^ (*s++) ^ (i >> 5);
  case 16: i ^= (i << 7) ^ (*s++) ^ (i >> 3);
  case 15: i ^= (i << 11) ^ (*s++) ^ (i >> 5);
  case 14: i ^= (i << 7) ^ (*s++) ^ (i >> 3);
  case 13: i ^= (i << 11) ^ (*s++) ^ (i >> 5);
  case 12: i ^= (i << 7) ^ (*s++) ^ (i >> 3);
  case 11: i ^= (i << 11) ^ (*s++) ^ (i >> 5);
  case 10: i ^= (i << 7) ^ (*s++) ^ (i >> 3);
  case 9: i ^= (i << 11) ^ (*s++) ^ (i >> 5);
  case 8: i ^= (i << 7) ^ (*s++) ^ (i >> 3);
  case 7: i ^= (i << 11) ^ (*s++) ^ (i >> 5);
  case 6: i ^= (i << 7) ^ (*s++) ^ (i >> 3);
  case 5: i ^= (i << 11) ^ (*s++) ^ (i >> 5);
  case 4: i ^= (i << 7) ^ (*s++) ^ (i >> 3);
  case 3: i ^= (i << 11) ^ (*s++) ^ (i >> 5);
  case 2: i ^= (i << 7) ^ (*s++) ^ (i >> 3);

```

```

case 1: i ^= (i << 11) ^ (*s++) ^ (i >> 5);
case 0: break;
default:
    i ^= (i << 7) ^ (*s++) ^ (i >> 3);
    i ^= (i << 11) ^ (*s++) ^ (i >> 5);
    i ^= (i << 7) ^ (*s++) ^ (i >> 3);
    i ^= (i << 11) ^ (*s++) ^ (i >> 5);
    i ^= (i << 7) ^ (*s++) ^ (i >> 3);
    i ^= (i << 11) ^ (*s++) ^ (i >> 5);
    i ^= (i << 7) ^ (*s++) ^ (i >> 3);
    i ^= (i << 11) ^ (*s++) ^ (i >> 5);
    i ^= (i << 7) ^ (*s++) ^ (i >> 3);
    i ^= (i << 11) ^ (*s++) ^ (i >> 5);

}
return i;
}

```

To hash a string, its characters are combined mathematically as integers. At most the first ten characters are used. [Unicon uses up to the first ten and the last ten, to distinguish long strings such as identifiers with differences at either end.](#) The limit on the number of characters used in the hash is important because strings can be very long and adding all the characters does not improve the hashing sufficiently to justify the time spent in the computation. A maximum of ten or twenty is, however, *ad hoc*. To provide a measure of discrimination between strings with the same initial substring, the length of the string is added to the sum of the characters.

Icon's technique for hashing strings is not sophisticated, and others that produce better hashing results are known. However, the computation is simple, easy to write in C, and works well on most data. Unicon's technique is adapted from one due to Arash Partow (<http://www.partow.net/programming/hashfunctions/>), with length caps and loop unrolling. It was validated empirically on a wide range of data sets.

For a numeric type, the hash value is derived from the number. In the case of a cset, the words containing the bits for the cset are combined using the exclusive-or operation.

The remaining data types pose an interesting problem. Hash computation must be based on attributes of a value that are invariant with time. Some types, such as files, have such attributes. On the other hand, there is no time-invariant attribute that distinguishes one list from another. The size of a list may change, the elements in it may change, and even its location in memory may change as the result of garbage collection. For a list, its only time-invariant attribute is its type.

This presents a dilemma—the type of such a value can be used as its hash number, but if that is done, all values of that type are in the same slot and have the same hash number. Lookup for these

values degenerates to a linear search. The alternative is to add some time-invariant attribute, such as a serial number, to these values. Icon does this, at the cost of increasing the size of every such value.

RETROSPECTIVE: Few programming languages support sets or tables with Icon's generality. The implementation of sets and tables provides a clear focus on the generality of descriptors and the uniformity with which different kinds of data are treated in Icon.

Since sets and tables may be very large, efficient lookup is an important concern. The hashing and chaining technique used is only one of many possibilities. However, there must be a mechanism for determining the equivalence of values independent of the structure in which they are stored.

The fact that elements in tables are accessed by subscripting expressions introduces several complexities. In particular, the fact that the contents of the table that is subscripted may change between the time the subscripting expression is evaluated and the time it is dereferenced or assigned to introduces the necessity of two lookups for every table reference.

Hashing a variety of different types of data raises interesting issues. The hashing techniques used by Icon are not sophisticated and there is considerable room for improvement. The trade-offs involved are difficult to evaluate, however.

## EXERCISES

1. 1.1 Contrast sets and csets with respect to their implementation, their usefulness in programming, and the efficiency of operations on them.
- 1.2 Give an example of a situation in which the heterogeneity of sets is useful in programming.
- 1.3 How much space does an empty set occupy?
- 1.4 Diagram the structures resulting from the evaluation of the following expressions:  
`t := table()`  
`t[t] := t`
- 1.5 There are many sophisticated data structures that are designed to ensure efficient lookup in data aggregates like sets and tables (Gonnet 1984). Consider the importance of speed of lookup in sets and tables in Icon and the advantages that these more sophisticated data structures might supply.
- 1.6 Some of the more sophisticated data structures mentioned in the preceding exercise have been tried experimentally in Icon and either have introduced unexpected implementation problems or have not provided a significant improvement in performance. What are possible reasons for these disappointing results?
- 1.7 Icon goes to a lot of trouble to avoid adding table-element blocks to a table unless an assignment is made to them. Suppose a table-element block were simply added when a reference was made to an entry value that is not in the table.

- How would this simplify the implementation?
- What positive and negative consequences could this change have on the running speed and space required during program execution?
- Give examples of types of programs for which the change would have positive and negative effects on performance, respectively.
- Would this change be transparent to the Icon programmer, not counting possible time and space differences?

1. 1.1 There is space in a table-element trapped-variable block to put the default value for the table. Why is this not done?

1.2 What is the consequence of evaluating the following expressions?

```
t := table(0)
t[37] := 2
write(t[37], t := table(1))
```

What would happen if the last line given previously were

```
write(t[37], t := list(100,3))
```

or

```
write(t[37], t := "hello")
```

1. 1.1 Give examples of different strings that have the same hash numbers.
- 1.2 Design a method for hashing strings that produces a better distribution than the current one.
- 1.3 What attribute of a table is time-invariant?
- 1.4 What kinds of symptoms might result from a hashing computation based on an attribute of a value that is not time-invariant?

# Chapter 8

## The Interpreter

**PERSPECTIVE:** The interpreter provides a software realization of Icon's virtual machine. This machine is stack-based. The basic units on which the Icon virtual machine operates are descriptors. The instructions for the virtual machine consist of operations that manipulate the stack, call C functions that carry out the built-in operations of Icon, and manage the flow of control. The Icon interpreter executes these virtual machine instructions. It consists of a loop in which a virtual machine instruction is fetched and control is transferred to a section of code to perform the corresponding operation.

### 8.1 Stack-Based Evaluation

Virtual machine instructions typically push and pop data on the interpreter stack. The interpreter stack, which is distinct from the stack used for calls of C functions, is an array of words. The variable `sp` points to the last word pushed on the interpreter stack. Pushing increments `sp`, while popping decrements it. When the interpreter executes code that corresponds to a built-in operation in Icon, it pushes descriptors for the arguments on the interpreter stack and calls a C function corresponding to that operation with a pointer to the place on the interpreter stack where the arguments begin. A null descriptor is pushed first to serve as a "zeroth" argument (`Arg0`) that receives, by convention, the result of the computation and becomes the top descriptor on the stack when the C function returns. On a more conventional virtual machine, the result of the computation would be pushed on the stack, instead of being returned in an argument. The latter method is more convenient in Icon.

To illustrate this basic mechanism, consider the expression

`?10`

which produces a randomly selected integer between 1 and 10, inclusive. The corresponding virtual machine instructions are

```

pnull      # push null descriptor for the result
int      10 # push descriptor for the integer 10
random    # compute random value

```

The instructions `pnull` and `int` operate directly on the stack. The instruction `random` calls a C function that computes random values.

The `pnull` instruction pushes a null descriptor:

The `int` instruction pushes a descriptor for the integer 10:

Suppose that the C function for `random` computes 3. It replaces the null value of Arg0 by a descriptor for the integer 3. When it returns, `sp` is set to point to Arg0 and the situation is

## 8.2 Virtual Machine Instructions

The various aspects of expressions that appear in Icon source-language programs are reflected, directly or indirectly, in the instruction set for the Icon virtual machine. References to constants (literals) and identifiers have direct correspondences in the instruction set of the virtual machine. There is a virtual machine instruction for each source-language operator. This is possible, since the

meaning of an operation is fixed and cannot be changed during program execution. The meaning of a function call, however, cannot be determined until it is evaluated, and there is a single virtual machine instruction for function invocation. The invocation of functions is described in detail in Chapter 10.

There are several virtual machine instructions related to control structures and the unique aspects of expression evaluation in Icon. These are discussed in the next two chapters. A complete list of virtual machine instructions is given in Appendix B.

### 8.2.1 Constants

Four kinds of data can be represented literally in Icon programs: integers, strings, csets, and real numbers. The four corresponding virtual machine instructions are

int	n	# integer n
str	n, a	# string of length n at address a
cset	a	# cset block at address a
real	a	# real block at address a

The values of integer literals appear as arguments of int instructions. In the case of strings, the two arguments give its length and the address of its first character.

The string itself is constructed by the linker and is loaded into memory from the icode file. For csets and real numbers, the linker constructs blocks, which are also loaded from the icode file. These blocks are identical in format to blocks that are constructed during program execution.

The virtual machine instructions str, cset, and real push appropriate descriptors to reference the data as it appears in the icode. For example, the virtual machine instructions for

```
"aeiou"
```

are

```
pnull
str    5, a
random
```

where `a` is the address of the string "aeiou". The pnull instruction pushes a null descriptor as in the previous example:

The `str` instruction constructs a descriptor for the string "aeiou":

If `random` produces the string "o", this string replaces the null descriptor and the stack becomes

In reality, things are a bit more complicated. See Section 8.2.5.

## 8.2.2 Identifiers

From the viewpoint of the interpreter, there are four kinds of identifiers: global identifiers, static identifiers, local identifiers, and arguments. The values of global and static identifiers are in arrays of descriptors at fixed locations in memory. The values of local identifiers and arguments, on the other hand, are kept on the stack as part of the information associated with a procedure call.

The values of the arguments in the call of a procedure are pushed on the stack as the result of the evaluation of expressions prior to the invocation of the procedure. The initial null values for local identifiers are pushed on the stack when the procedure is called.

Consider the following procedure declaration:

```

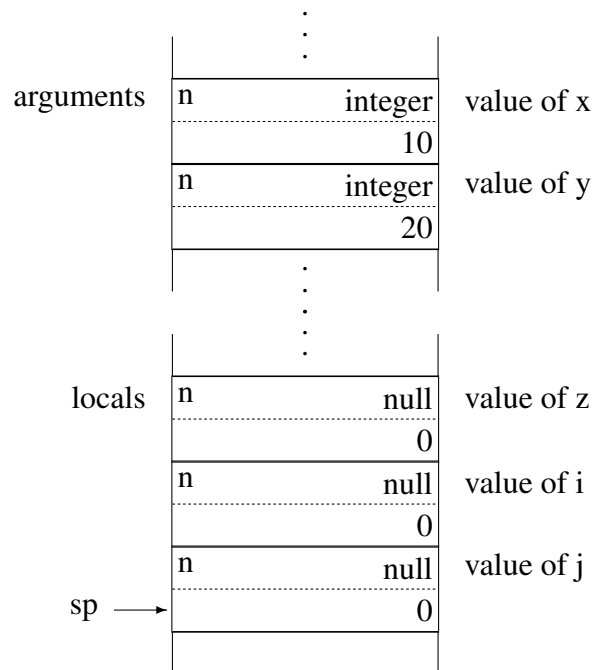

procedure p(x,y)
  local z, i, j
  j := 1
  z := x
  ...
end

```

In the evaluation of a call to this procedure such as

`p(10,20)`

the stack is in the following state prior to the evaluation of the first expression in p:

The portion of the stack between the arguments and local identifiers is fixed in size and contains information that is saved when a procedure is called. This information is described in Chapter 10.

There are four virtual machine instructions for constructing variable descriptors:

global	n
static	n
arg	n
local	n

Identifiers of each kind are numbered starting at zero. Consequently,

arg	0
-----	---

pushes a variable descriptor for the first argument. In each case, the descriptor that is pushed on the stack is a variable that points to the descriptor for the value of the corresponding identifier.

Consider the expression

j := 1

The corresponding virtual machine instructions are

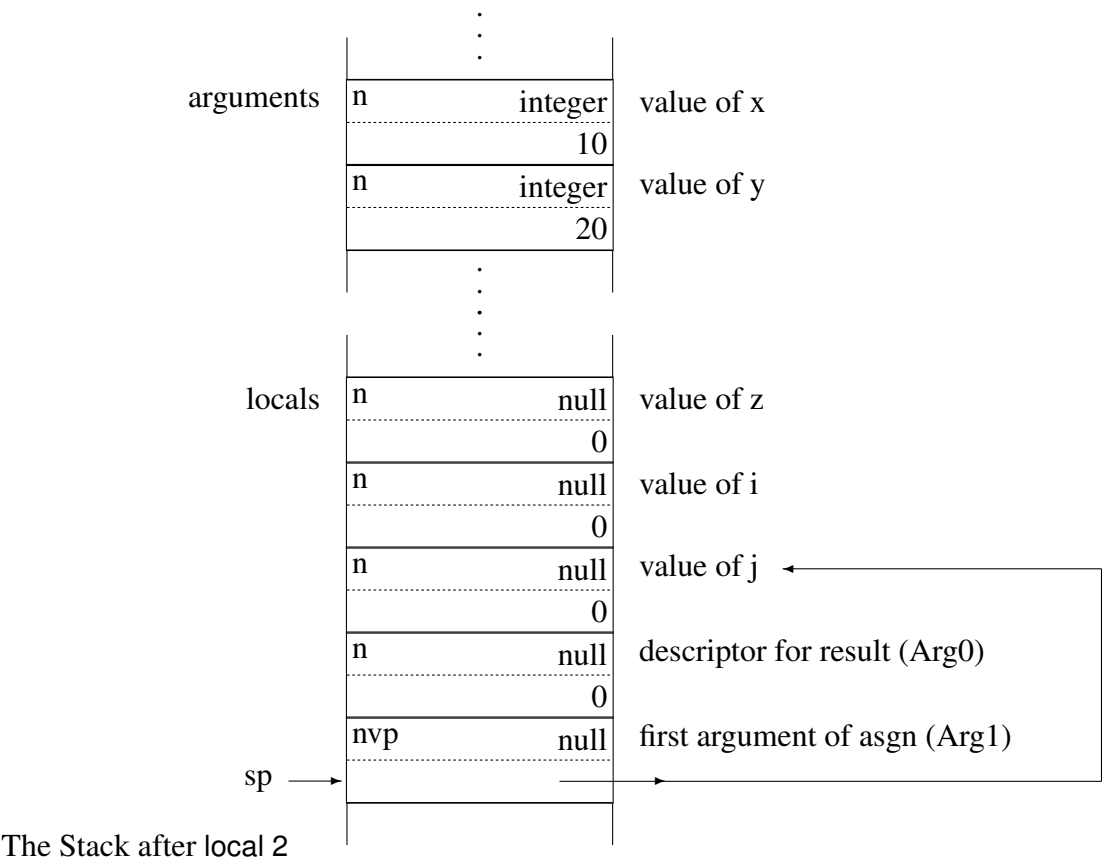

```

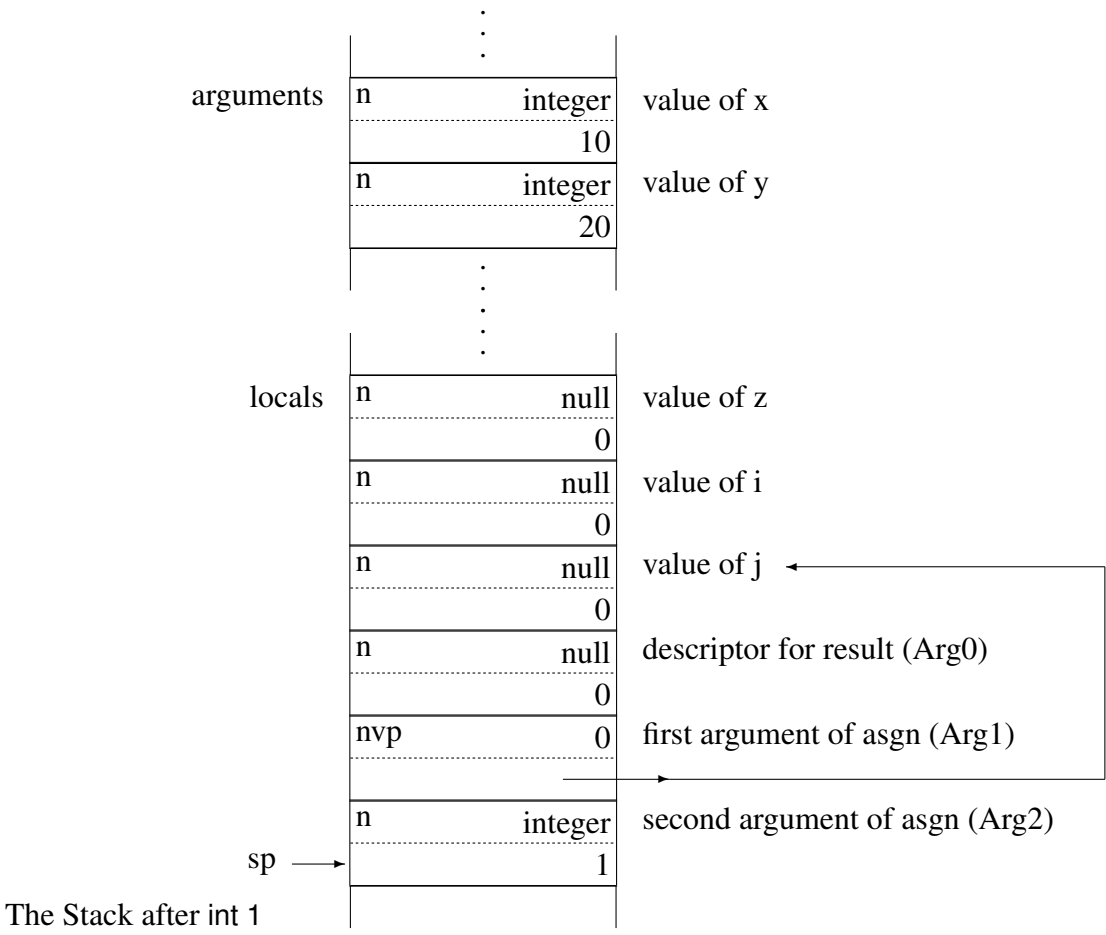

pnull      # push null descriptor for the result
local  2    # push variable descriptor for j
int      1   # push descriptor for the integer 1
asgn      # perform assignment

```

When these instructions are interpreted, the succession of stack states is

The Stack after asgn

Note that asgn assigns the value of its second argument to j and overwrites Arg0 with a variable descriptor, which is left on the top of the stack.

Similarly, the virtual machine instructions for

`z := x`

are

```

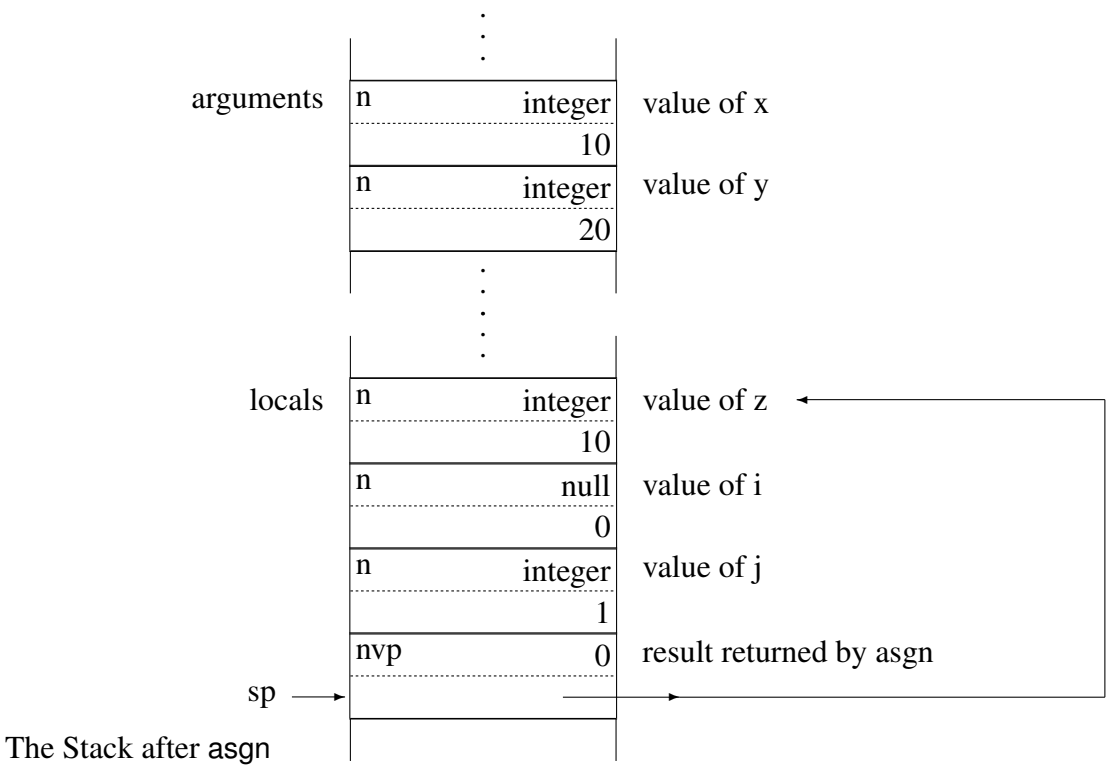

pnull
local    0
arg      0
asgn

```

the states of the stack are

### 8.2.3 Operators

There is a virtual machine instruction for each of the forty-two operators in Icon. The instructions random and asgn described previously are examples. Casting Icon operators as virtual machine instructions masks a considerable amount of complexity, since few Icon operators are simple. For example, although  $x + y$  appears to be a straightforward computation, it involves checking the types of  $x$  and  $y$ , converting them to numeric types if they are not already numeric, and terminating with an error message if this is not possible. If  $x$  and  $y$  are numeric or convertible to numeric, addition is performed. Even this is not simple, since the addition may be integer or floating-point, depending on the types of the arguments. For example, if  $x$  is an integer and  $y$  is a real number, the integer is converted to a real number. None of these computations is evident in the virtual machine instructions produced for this expression, which are

```
pnull
local    x
local    y
plus
```

In the instructions given previously, the indices that are used to access identifiers have been replaced by the names of the identifiers, which are assumed to be local. This convention is followed in subsequent virtual machine instructions for ease of reading.

Augmented assignment operations do not have separate virtual machine instructions. Instead, the instruction `dup` first pushes a null descriptor and then pushes a duplicate of the descriptor that was previously on top of the stack. For example, the virtual machine instructions for

`i += 1`

are

```
pnull
local    i
dup
int      1
plus
asgn
```

The stack after the execution of `local` is

The execution of `dup` produces

The `dup` instruction simply takes the place of the `pnull` and second `local` instructions in the virtual machine instructions for

`i := i + 1`

which are

```

pnull
local    i
pnull
local    i
int      1
plus
asgn

```

In this case, only a single local instruction is avoided. If the variable to which the assignment is made is not just an identifier but, instead, a more complicated construction, as in

```
a[j] += 1
```

substantial computation may be saved by duplicating the result of the first argument expression instead of recomputing it.

## 8.2.4 Functions

While the meaning of an operation is fixed and can be translated into a specific virtual machine instruction, the meaning of a function call can change during program execution. The value of the function also can be computed. as in

```
(p[i])(x, y)
```

The general form of a call is

```
expr0(expr1, expr2, ..., exprn)
```

The corresponding virtual machine instructions are

```

code for expr0
code for expr1
code for expr2
...
code for exprn
invoke n

```

The invoke instruction is relatively complicated, since the value of *expr0* may be a procedure, an integer (for mutual evaluation), or even a value that is erroneous. Function invocation is discussed in detail in Chapter 10.

## 8.2.5 Self-Modifying Instructions

Seven opcodes, including several described in the preceding sections, contain operands whose values are addresses within the virtual machine icode. The linker cannot know these run-time addresses, so instead, it generates the instructions with byte offsets, relative to the current instruction. At runtime the interpreter obtains the address in question by adding the current instruction pointer to the offset. In order to avoid repeating this calculation every time the instruction executes, the interpreter stores the pointer in place of the offset and modifies the opcode to indicate that the offset has been converted to a pointer. The self modifying instructions and their address-holding counterparts are:

str	Astr
cset	Astr
real	Areal
global	Aglobal
static	Astatic
goto	Agoto
mark	Amark

The details of the str instruction illustrate the code for self-modifying instructions. There are several points of interest. The opcode must be modified from Op\_Str to Op\_Astr and its offset operand modified to contain a pointer. Depending on whether Concurrent is enabled, the self-modification of the instruction is done by either two "Put" macros (PutOp(Op\_Astr) on the current opcode and PutWord(opnd)), or by a PutInstr(Op\_Astr, opnd, 2) after the instruction pointer is referring to the operand. This is because these self-modifying instructions create a race condition when executed concurrently and thus require mutex locks. After (potentially) waiting to obtain a lock, the instruction must check again to see if a competing thread has already modified its opcode, and if so, it jumps down to the code for Op\_Astr.

```

        case Op_Str: /* string */
#ifdef Concurrent
            MUTEX_LOCKID(MTX_OP_ASTR);
            if (ipc.op[-1] == Op_Astr) {
                MUTEX_UNLOCKID(MTX_OP_ASTR); goto L_ast; }
#else /*Concurrent*/
            PutOp(Op_Astr);
#endif /*Concurrent*/
            PushVal(GetWord)

        ...

```

```

        opnd = (word)strcons + GetWord;

#ifdef Concurrent
        PutInstr(Op_Astr, opnd, 2);
#else /*Concurrent*/
        PutWord(opnd);
#endif /*Concurrent*/
        PushAVal(opnd);
        InterpEVValD((dptr)(rsp-1), e_literal);

        MUTEX_UNLOCKID(MTX_OP_ASTR);
        break;

case Op_Astr: /* string, absolute address */
L_ast:
        PushVal(GetWord);
        PushAVal(GetWord);
        InterpEVValD((dptr)(rsp-1), e_literal);
        break;

```

## 8.3 The Interpreter Proper

### 8.3.1 The Interpreter Loop

The interpreter, which is called `interp()`, is basically simple in structure. It maintains a location in the icode (`ipc`) and begins by fetching the instruction pointed to by `ipc` and incrementing `ipc` to the next location. It then branches to a section of code for processing the virtual machine instruction that it fetched. The interpreter loop is

```

for (;;) {
    op = GetWord;
    switch (op) {
        ...
        case Op_Asgn:
            ...
        case Op_Plus:
            ...
    }
    continue;
}

```

```

        ...
    }

```

where `GetWord` is a macro that is defined to be `(*ipc++)`.

Macros are used extensively in the interpreter to avoid repetitious coding and to make the interpreter easier to read. The coding is illustrated by the case clause for the instruction `plus`:

```

case Op_Plus: /* e1 + e2 */
    Setup_Op(2);
    DerefArg(1);
    DerefArg(2);
    Call_Op;
    break;

```

`Setup_Op(n)` sets up a pointer to the address of `Arg0` on the interpreter stack. The resulting code is

```
rargp = (dptr)(sp - 1) - n;
```

The value of `n` is the number of arguments on the stack.

`DerefArg(n)` dereferences argument `n`. If it is a variable, it is replaced by its value. Thus, dereferencing is done in place by changing descriptors on the interpreter stack.

`Call_Cond` calls the appropriate C function with a pointer to the interpreter stack as provided by `Setup_Op(n)`. The function itself is obtained by looking up `op` in an array of pointers to functions. The code produced by `Call_Cond` is (almost)

```

(*(optab[op]))(rargp);
sp = (word *)rargp + 1;

```

In the case where a C function produces a result, as `plus` always does, that result is placed in the `Arg0` descriptor on the interpreter stack, as illustrated by the examples in Chapters 4 and 5. The interpreter adjusts `sp` to point to the `v-word` of `Arg0`. The `break` transfers control to the end of the switch statement, where a `continue` statement transfers control to the beginning of the interpreter loop, and the next instruction is fetched.

As illustrated earlier, some virtual machine instructions have operands, which follow the instructions in the icode. The interpreter code for such an instruction fetches its operands. An example is

```
int n
```

The interpreter code for `int` is

```

case Op_Int: /* integer */
  PushVal(D_Integer);
  PushVal(GetWord);
  break;

```

PushVal(x) pushes x onto the interpreter stack. Thus, the descriptor for the integer is constructed by first pushing the constant D\_Integer for the d-word and then pushing the fetched operand for the v-word.

### 8.3.2 Interpreter State Variables

The state of the interpreter is characterized by several variables, called *i-state variables*. Two i-state variables mentioned previously are sp, the interpreter stack pointer, and ipc, the interpreter “program counter.”

The interpreter also pushes frames on the interpreter stack when procedures are called. Such frames are analogous to the frames pushed on the C stack when a C function is called, and contain information (typically i-state variables) that is saved when a procedure is called and restored when a procedure returns. There are other kinds of frames for special aspects of expression evaluation; these are described in Chapter 9. Pointers to frames are themselves i-state variables.

The proper maintenance of i-state variables is a central aspect of the interpreter and is discussed in detail in the next two chapters.

Retrospective: The interpreter models, in software, the hardware of a cpu. The instruction fetch, the execution of operations, and the flow of control are basically the same as that in hardware execution, as is the use of a stack.

An interpreter offers great flexibility. It is easy to add virtual machine instructions, change existing ones, or change how they are implemented. Tracking and monitoring also are easy to add. The interpreter is machine-independent and portable. These advantages outweigh the loss in efficiency associated with emulating hardware in software.

### EXERCISES

1. Why is it advantageous for the first argument of str to be the length of the string, rather than its address?
2. Show the states of the stack for the execution of the virtual machine instructions for the following Icon expressions:

```

i := i + 1
l := ???j

```

3. Give an example for which

$\text{expr1} := \text{expr1} + \text{expr2}$

produces a different result from

$\text{expr1} += \text{expr2}$

4. Describe, in general terms, what would be involved in adding a new operator to Icon.
5. Describe, in general terms, what would be involved in adding a new kind of literal to Icon.
6. Suppose that functions were bound at translation time instead of being source-language values. How might the virtual machine be modified to take advantage of such a feature? What effect would this have on the interpreter?

## Chapter 9

# Expression Evaluation

PERSPECTIVE: The preceding chapter presents the essentials of the interpreter and expression evaluation as it might take place in a conventional programming language in which every expression produces exactly one result. For example, expressions such as

```
i := j
k := i + j
i += ?k
```

each produce a single result: they can neither fail nor can they produce sequences of results.

The one feature of Icon that distinguishes it most clearly from other programming languages is the capacity of its expression-evaluation mechanism to produce no result at all or to produce more than one result. From this capability come unconventional methods of controlling program flow, novel control structures, and goal-directed evaluation.

The generality of this expression-evaluation mechanism alone sets Icon apart from other programming languages. While generators, in one form or another, exist in a number of programming languages, such as IPL-V (Newell 1961), CLU (Liskov 1981), Alphard (Shaw 1981), and SETL (Dewar, Schonberg, and Schwartz 1981), such generators are limited to specific constructs, designated contexts, or restricted types of data. Languages with pattern-matching facilities, such as SNOBOL4 (Griswold, Poage, and Polonsky 1971), InterLisp (Teitelman 1974), and Prolog (Clocksin and Mellish 1981), generate alternative matches, but only within pattern matching.

Just as Icon's expression-evaluation mechanism distinguishes it from other programming languages, it is also one of the most interesting and challenging aspects of Icon's implementation. Its applicability in every context and to all kinds of data has a pervasive effect on the implementation.

## 9.1 Bounded Expressions

A clear understanding of the semantics of expression evaluation in Icon is necessary to understand the implementation. One of the most important concepts of expression evaluation in Icon is that of a *bounded expression*, within which backtracking can take place. However, once a bounded expression has produced a result, it cannot be resumed for another result. For example, in

```
write(i = find(s1,s2))
```

`find` may produce a result and may be resumed to produce another result if the comparison fails. On the other hand, in

```
write(i = find(s1, s2))
write(j = find(s1, s3))
```

the two lines constitute separate expressions. Once the evaluation of the expression on the first line is complete, it cannot be resumed. Likewise, the evaluation of the expression on the second line is not affected by whether the expression on the first line succeeds or fails. However, if the two lines are joined by a conjunction operation, as in

```
write(i = find(s1, s2)) &
write(i = find(s1, s3))
```

they are combined into a larger single expression and the expression on the second line is not evaluated if the expression on the first line fails. Similarly, if the expression on the first line succeeds, but the expression on the second line fails, the expression on the first line is resumed.

The reason for the difference in the two cases is obscured by the fact that the Icon translator automatically inserts a semicolon at the end of a line on which an expression is complete and for which a new expression begins on the next line.

Consequently, the first example is equivalent to

```
write(i = find(s1, s2));
write(i = find(s1, s3))
```

The difference between the semicolon and the conjunction operator is substantial. A semicolon bounds an expression, while an operator binds its operands into a single expression.

Bounded expressions are enclosed in ovals in the following examples to make the extent of backtracking clear. A compound expression, for example, has the following bounded expressions:

$$\{ \text{ } \overline{\text{expr}_1}; \overline{\text{expr}_2}; \dots; \text{expr}_n \text{ } \}$$

Note that  $expr_n$  is not, of itself, a bounded expression. However, it may be part of a larger bounded expression, as in

$$\{ \textcircled{expr_1}; \textcircled{expr_2}; \dots; expr_n \} = 1;$$

Here  $expr_n$  is part of the bounded expression for the comparison operator. The entire enclosing bounded expression is a consequence of the final semicolon. In the absence of the context provided by this semicolon, the entire expression might be part of a larger enclosing bounded expression, and so on.

The separation of a procedure body into a number of bounded expressions, separated by semicolons (explicit or implicit) and other syntactic constructions, is very important. Otherwise, a procedure body would consist of a single expression, and failure of any component would propagate throughout the entire procedure body. Instead, control backtracking is limited in scope to abounded expression, as is the lifetime (and hence stack space) for temporary computations.

Bounded expressions are particularly important in control structures. For example, in the if-then-else control structure, the control expression is bounded but the other expressions are not:

$$\text{if } \textcircled{expr_1} \text{ then } expr_2 \text{ else } expr_3$$

As with the compound expression illustrated earlier,  $expr_2$  or  $exp_3$  (whichever is selected) may be the part of a larger bounded expression. An example is

$$\text{write ( if } \textcircled{i < j} \text{ then } i \text{ to } j \text{ else } j \text{ to } i )$$

If the control expression were not a separate bounded expression, the failure of  $expr_2$  or  $exp_3$  would result in backtracking into it and the if-then-else expression would be equivalent to

$$(expr_1 \ \& \ expr_2) \mid expr_3$$

which is hardly what is meant by if-then-else.

In a while-do loop, the control expression and the expression in the do clause are both bounded:

$$\text{while } \textcircled{expr_1} \text{ do } \textcircled{expr_2}$$

The two bounded expressions ensure that the expressions are evaluated independently of each other and any surrounding context. For example, if  $expr_2$  fails, there is no control backtracking into  $expr_1$ .

### 9.1.1 Expression Frames

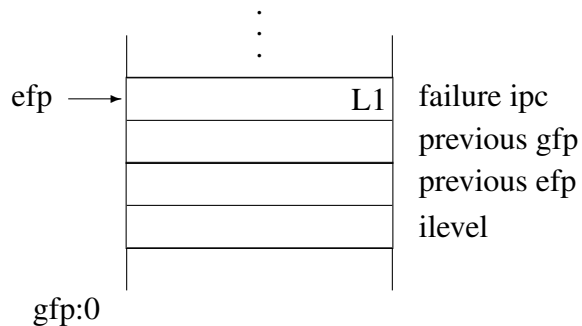

In the implementation of Icon, the scope of backtracking is delineated by *expression frames*. The virtual machine instruction

```
mark    L1
```

starts an expression frame. If the subsequent expression fails, ipc is set to the location in the icode that corresponds to L1. The value of ipc for a label is relative to the location of the icode that is read in from the icode file. For simplicity in the description that follows, the value of ipc is referred to just by the name of the corresponding label.

The mark instruction pushes an *expression frame marker* onto the stack and sets the expression frame pointer, efp, to it. Thus, efp indicates the beginning of the current expression frame. There is also a generator frame pointer, gfp, which points to another kind of frame that is used to retain information when an expression suspends with a result and is capable of being resumed for another. Generator frames are described in Sec. 9.3. The mark instruction sets gfp to zero, indicating that there is no suspended generator in a new expression frame.

An expression frame marker consists of four words: the value ipc for the argument of mark (called the failure ipc), the previous efp, the previous gfp, and ilevel, which is related to suspended generators:

An expression frame marker is declared as a C structure:

```

struct ef_marker {                /* expression frame marker */
    word *ef_failure;             /* failure ipc */
    struct ef_marker *ef_efp;     /* efp */
    struct gf_marker *ef_gfp;     /* gfp */
    word ef_ilevel;               /* ilevel */
}

```

This structure is overlaid on the interpreter stack in order to reference its components. The code for the mark instruction is

```

case Op_Mark:      /* create expression frame marker */
    newefp = (struct ef_marker*)(sp + 1);
    opnd = GetWord;
    opnd += (word)ipc;
    newefp->ef_failure = (word *)opnd;
    newefp->ef_gfp = gfp;
    newefp->ef_efp = efp;
    newefp->ef_ilevel = ilevel;
    sp += Wsizeof(*efp);
    efp = newefp;
    gfp = 0;
    break;

```

The macro Wsizeof(x) produces the size of x in words.

An expression frame is removed by the virtual machine instruction  
unmark

which restores the previous efp and gfp from the current expression frame marker and removes the current expression frame by setting sp to the word just above the frame marker.

The use of mark and unmark is illustrated by

if *expr*<sub>1</sub> then *expr*<sub>2</sub> else *expr*<sub>3</sub>

for which the virtual machine instructions are

```

mark L1
code for expr1
unmark
code for expr2
goto L2
L1:
code for expr3
L2:

```

The mark instruction creates an expression frame for the evaluation of *expr*<sub>1</sub>. If *expr*<sub>1</sub> produces a result, the unmark instruction is evaluated, removing the expression frame for *expr*<sub>1</sub>, along with the result produced by *expr*<sub>1</sub>. Evaluation then proceeds in *expr*<sub>2</sub>.

If *expr*<sub>1</sub> fails, control is transferred to the location in the icode corresponding to L1 and the unmark instruction is not executed. In the absence of generators, failure also removes the current expression frame, as described in Sec. 9.2.

It is necessary to save the previous value of efp in a new expression marker, since expression frames may be nested. This occurs in interesting ways in some generative control structures, which are discussed in Sec. 9.4. Nested expression frames also occur as a result of evaluating compound expressions, such as

while  $\textcircled{expr_1}$  do if  $\textcircled{expr_2}$  then  $expr_3$

## 9.2 Failure

The interesting aspects of implementing expression evaluation in Icon can be divided into two cases: without generators and with generators. The possibility of failure in the absence of generators is itself of interest, since it occurs in other programming languages, such as SNOBOL4. This section describes the handling of failure and assumes, for the moment, that there are no generators. The next section describes generators.

In the absence of generators, if failure occurs anywhere in an expression, the entire expression fails without any further evaluation. For example, in the expressions

```
i := numeric(s)
line := read(f)
```

if `numeric(s)` fails in the first line, the assignment is not performed and evaluation continues immediately with the second line. In the implementation, this amounts to removing the current expression frame in which failure occurs and continuing with `ipc` set to the failure `ipc` from its expression frame marker.

The virtual machine instructions for the previous example are

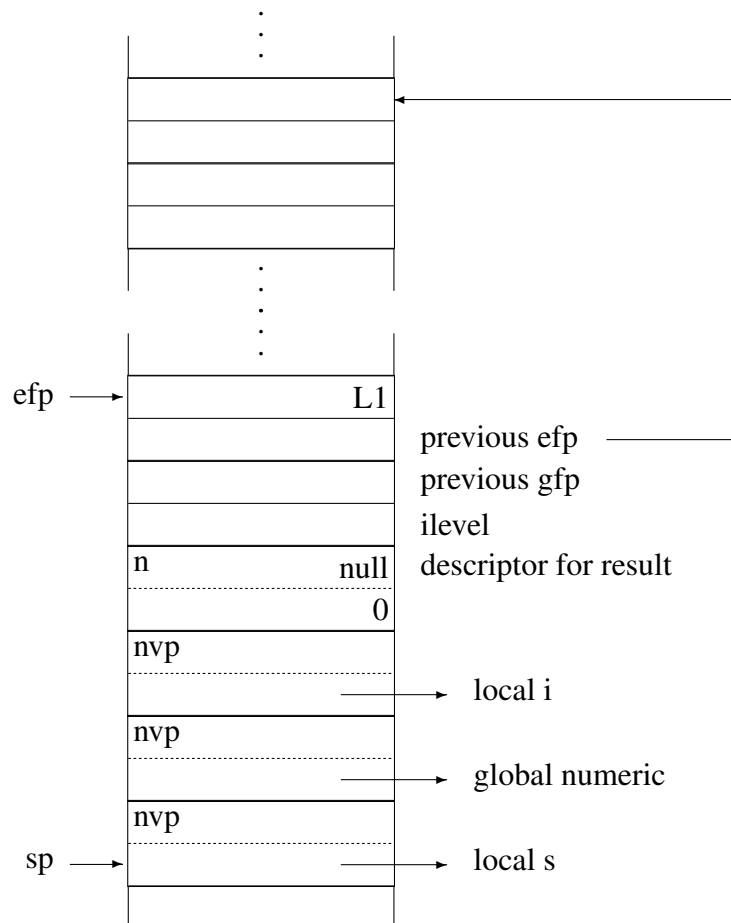

```
mark L1
pnull
local i
global numeric
local s
invoke 1
asgn
unmark
L1:
mark L2
pnull
local line
global read
local f
invoke 1
asgn
unmark
L2:
```

Prior to the evaluation of the expression on the first line, there is some expression frame on the stack:

The instruction  
mark L1

starts a new expression frame. The execution of subsequent virtual machine instructions pushes additional descriptors. The state of the stack when numeric is called by the invoke instruction is

If numeric(s) fails, `efp` and `sp` are reset, so that the stack is in the same state as it was prior to the evaluation of the expression on the first line:

Control is transferred to the location in the icode corresponding to L1, and the execution of  
 mark      L2

starts a new expression frame by pushing a new expression frame marker onto the stack.

It is worth noting that failure causes only the current expression frame to be removed and changes `ipc` to the failure `ipc`. Any remaining virtual machine instructions in the current expression frame are bypassed; failure is simple and quick.

Failure can occur at three levels: directly from the virtual machine instruction `efail`, from a C function that implements an operator or function (as in the previous example), or from an Icon procedure.

When a conditional operator or function returns, it signals the interpreter, indicating whether it is producing a result or failing by using one of the RTL forms of `return` or `fail`. These RTL constructs simply produce return statements with different returned values.

The code in the interpreter for a conditional operation is illustrated by

```
case Op_Numlt:    /* e1 < e2 */
    Setup_Op(2);
    DerefArg(1);
    DerefArg(2);
    Call_Cond;
```

The macro `Call_Cond` is similar to `Call_Op` described in Sec. 8.3.1, but it tests the signal returned by the C function. If the signal corresponds to the production of a result, the `break` is executed and control is transferred to the beginning of the interpreter loop to fetch the next virtual machine instruction. On the other hand, if the signal corresponds to failure, control is transferred to the place in the interpreter that handles failure, `efail`.

An Icon procedure can fail in three ways: by evaluating the expression fail, by the failure of the argument of a return expression, or by flowing off the end of the procedure body. The virtual machine instructions generated for the three cases are similar. For example, the virtual machine instructions for

```
    if i < j then fail else write(j)
are
```

```
    mark      L1
    pnull
    local     i
    local     j
    numlt
    unmark
    pfail
L1:
    global    write
    local     j
    invoke    1
```

The virtual machine instruction pfail first returns from the current procedure call (see Sec. 10.3), and then transfers to efail.

## 9.3 Generators and Goal-Directed Evaluation

The capability of an expression not to produce a result is useful for controlling program flow and for bypassing unneeded computation, but generators add the real power and expressiveness to the expression-evaluation semantics of Icon. It should be no surprise that generators also present difficult implementation problems. There are several kinds of generators, including those for control structures, functions and operators, and procedures. While the implementation of the different kinds of generators varies in detail, the same principles apply to all of them.

As far as using a result of an expression in further computation is concerned, there is no difference between an expression that simply produces a result and an expression that produces a result and is capable of being resumed to produce another one. For example, in

```
i := numeric("2")
j := upto('aeiou', "Hello world")
```

the two assignment operations are carried out in the same way, even though upto() is a generator and numeric() is not.

Since such contexts cannot be determined, in general, prior to the time the expressions are evaluated, the implementation is designed so that the interpreter stack is the same, as far as enclosing expressions are concerned, whether an expression returns or suspends. For the previous example, the arguments to the assignment operation are in the same relative place in both cases.

On the other hand, if a generator that has suspended is resumed, it must be capable of continuing its computation and possibly producing another result. For this to be possible, both the generator's state and the state of the interpreter stack must be preserved. For example, in

```
j := (i < upto('aeiou', "Hello world"))
```

when the function upto() suspends, both i and the result produced by upto() must be on the stack as arguments of the comparison operation. However, if the comparison operation fails and upto() is resumed, the arguments of upto() must be on the stack as they were when upto() suspended. To satisfy these requirements, when upto() suspends, a portion of the stack prior to the arguments for upto() is copied to the top of the stack and the result produced by upto is placed on the top of the stack. Thus, the portion of the stack required for the resumption of upto() is preserved and the arguments for the comparison are in the proper place.

**Generator Frames.** When an expression suspends, the state of the interpreter stack is preserved by creating a *generator frame* on the interpreter stack that contains a copy of the portion of the interpreter stack that is needed if the generator is resumed. A generator frame begins with a generator frame marker that contains information about the interpreter state that must be restored if the corresponding generator is resumed. There are three kinds of generator frames that are distinguished by different codes:

- G\_Csusp      suspension from a C function
- G\_Esusp      suspension from an alternation expression
- G\_Psusp      suspension from a procedure

For the first two types of generators, the information saved in the generator frame marker includes the code for the type of the generator, the i-state variables efp, gfp, ipc, and the source-program line number at the time the generator frame is created:

The corresponding C structure is

```

struct gf_marker          /* generator frame marker */
    word gf_gentype;      /* type */
    struct ef_marker *gf_efp; /* efp */
    struct gf_marker *gf_gfp; /* gfp */
    word *gf_ipc          /* ipc */
    word gf_line;         /* line number */
};

```

Generators for procedure suspension contain, in addition, the i-state variable related to procedures. See Sec. 10.3.3.

As an example, consider the expression

```
write(i = (1 to 3));
```

The virtual machine instructions for this expression are:

```

mark      L1
global    write
local     i
pnull
int       1
int       3
push      1          # default increment
toby
numeq
invoke    1
unmark
L1 :

```

The state of the stack after execution of the first seven instructions is

The code in the interpreter for calling a generative operator with *n* arguments is

```
rargp = (struct descrip*)(sp - 1) - n;
signal = (*(optab[op]))(rargp);
goto C_rtn_term;
```

Note that *rargp* points to *Arg0* and is the argument of the call to the C function for the operator. The RTL function for *toby* is

```
operator{*} ... toby(from, to, by)
/*
 * arguments must be integers.
 */
if !cnv:C_integer(from) then
  runerr(101, from)
if !cnv:C_integer(to) then
  runerr(101, to)
if !cnv:C_integer(by) then
```

```

    runerr(101, by)
abstract {
    return integer
}
inline {
    /*
     * by must not be zero.
     */
    if (by == 0) {
        irunerr(211, by);
        errorfail;
    }
    /*
     * Count up or down (depending on relationship of from and
     * to) and suspend each value in sequence, failing when
     * the limit has been exceeded.
     */
    if (by > 0)
        for ( ; from <= to; from += by) {
            suspend C_integer from;
        }
    else
        for ( ; from >= to; from += by) {
            suspend C_integer from;
        }
    fail;
}
end

```

The RTL operator construct, which is similar to function, produces the C header

```
int Otoby(dptr r_args)
```

so that toby is called with a pointer to Arg0. Arguments with logical names Arg0, Arg1, and so forth are referred as r\_args[0], r\_args[1], and so on in the generated code.

When toby is called, it replaces its Arg0 descriptor by a descriptor for the integer from and suspends by using the RTL suspend construct rather than return.

The suspend statement *calls* interp() instead of returning to it. This leaves the call of toby intact with its variables preserved and also transfers control to interp() so that the next virtual machine instruction can be interpreted. However, it is necessary to push a generator marker on the interpreter stack and copy a portion of the interpreter stack, so that interpretation can continue

without changing the portion of the interpreter stack that toby needs in case it is resumed. This is accomplished by calling `interp()` with arguments that signal it to build a generator frame. The C code generated for `suspend` is

```
if ((signal = interp(G_Osusp, r_args RTTCURTSTATARG)) != A_Resume) {  
    return signal;  
}
```

The argument `G_Osusp` in the call of `interp()` indicates that a generator frame for C function that implements an operator is needed. The argument `r_args` points to the location on the interpreter stack where `Arg0` for the suspending C function is located. This location is the same as `rargp` in the call of `interp()` that called `upto`.

In this situation, `interp()` puts a generator frame marker on the interpreter stack and copies the portion of the interpreter stack from the last expression or generator frame marker through `cargp` onto the top of the interpreter stack:

The stack is exactly the same, as far as the execution of `numeq` is concerned, as it would have been if `toby` had simply returned. However, the arguments of `toby` (and the preceding arguments of `numeq`) are still intact, so that `toby` can be resumed. The generator frame is interposed between the two portions of the interpreter stack. The top of the stack corresponds to the evaluation of `write(i = 1);`

**Resumption.** Suppose the value of *i* in the previous example is 2. The comparison fails and control is transferred to *efail*, as it is in the case of all operations that fail. The code for *efail* is

```

case Op_Efail:
efail:
    /*
     * Failure has occurred in the current expression frame.
     */
    if (gfp == 0) {
        /*
         * There are no suspended generators to resume. Remove
         * the current expression frame, restoring values.
         *
         * If the failure ipc is 0, propagate failure to the
         * enclosing frame by branching back to efail.
         * This happens, for example, in looping control
         * structures that fail when complete.
         */
        ipc = efp->ef_failure;
        gfp = efp->ef_gfp;
        sp = (word *)efp - 1;
        efp = efp->ef_efp;
        if (ipc == 0)
            goto efail;
        break;
    }
    else {
        /*
         * There is a generator that can be resumed. Make
         * the stack adjustments and then switch on the
         * type of the generator frame marker.
         */
        register struct gf_marker *resgfp = gfp;
        tvoe = resgfp->gf_gentype;
        ipc = resgfp->gf_ipc;
        efp = resgfp->gf_efp;
        line = resgfp->gf_line;
        gfp = resgfp->gf_gfp;
    }

```

```

    sp = (word * )resgfp -1;

    switch (type) {
    case G_Csusp: {
        --ilevel;
        return A_Resumption;
        break;
    }
    case G_Esusp:
        goto efail;
    case G_Psusp:
        break;
    }
    break;
}

```

If there were no generator frame (if `gfp` were 0), the entire expression frame would be removed, and the expression would fail as described in Sec. 9.2. However, since there is a `C_Susp` generator frame, the stack is restored to the state it is in when toby suspended, and the values saved in the generator frame marker are *restored*:

All traces of the first execution of `numeq` have been removed from the stack. As shown by the code for `efail`, the call to `toby` is resumed by *returning* to it from `interp()` with the signal `A_Resumption`, which indicates another result is needed. When control is returned to `toby`, it changes its `Arg0` descriptor to the integer 2 suspends again:

The interpreter stack is exactly as it was when toby suspended the first time, except that the integer 2 is on the stack in place of the integer 1. The top of the stack corresponds to the evaluation of

`write(i = 2);`

Since the value of *i* is 2, *numeq* succeeds. It copies the value of its second argument to its *Arg0* descriptor and returns. The value 2 is written and the *unmark* instruction is executed, removing the entire expression frame from the stack.

**Goal-Directed Evaluation.** Goal-directed evaluation occurs when an expression fails and there are generator frames on the interpreter stack as the consequence of expressions that have suspended.

In the case of an expression such as

```
1 to upto(c, s)
```

*upto()* suspends first, followed by *toby*. These generator frames are linked together, with *gfp* pointing to the one for *toby*, which in turn contains a pointer to the one for *upto()*. In general, generator frames are linked together with *gfp* pointing to the one for the most recent suspension. This produces the last-in, first-out (depth-first) *order of* expression evaluation in Icon. Goal-directed evaluation occurs as a result of resuming a suspended expression when failure occurs in the surrounding expression frame.

**Removing C Frames.** Since C functions that suspend call the interpreter and the interpreter in turn calls C functions, expression evaluation typically results in a sequence of frames for calls on the C stack. When the evaluation of a bounded expression is complete, there may be frames on the C stack for generators, even though these generators no longer can be resumed.

In order to "unwind" the C stack in such cases, the *i*-state variable *ilevel* is used to keep track of the level of call of *interp()* by C functions. Whenever *interp()* is called, it increments *ilevel*. When an expression frame is created, the current value of *ilevel* is saved in it, as illustrated previously.

When the expression frame is about to be removed, if the current value of *ilevel* is greater than the value in the current expression frame, *ilevel* is decremented and the interpreter *returns* with a signal to the C function that called it to return rather than to produce another result. If the signal returned by *interp()* is *A\_Resumption*, the C function continues execution, while for any other signal the C function returns.

Since C functions return to *interp()*, *interp()* always checks the signal returned to it to determine if it produced a result or if it is unwinding. If it is unwinding, *interp()* returns the unwinding signal instead of continuing evaluation of the current expression.

Consider again the expression

```
write(i = (1 to 3));
```

for which the virtual machine instructions are

mark	L1
global	write
local	i
pnull	
int	1
int	3

```

push1          # default increment
toby
numeq
invoke 1
unmark
L1 :

```

When toby produces a result, it calls interp(). When the unmark instruction is executed, the C stack contains a frame for the call to toby and for its call to interp(). The code for unmark is

```

case Op_Unmark: /* remove expression frame */
    gfp = efp->ef_gfp;
    sp = (word *)efp -1;
    /*
     * Remove any suspended C generators.
     */
Unmark_uw:
    if (efp->ef_ilevel < ilevel) {
        --ilevel;
        return A_Unmark_uw;
    }
    efp = efp->ef_efp;
    break;

```

Note that in this case Suspend gets the return code A\_Unmark\_uw and in turn returns A\_Unmark\_uw to interp(). The section of code in interp() that checks the signal that is returned from C functions is

```

C_rtn_term:
    switch (signal) {
    case A_Failure:
        goto efail;
    case A_Unmark_uw:      /* unwind for unmark */
        goto Unmark_uw;
    case A_Lsusp_uw:      /* unwind for lsusp */
        goto Lsusp_uw;
    case A_Eret_uw:       /* unwind for eret */
        goto Eret_uw;
    case A_Pret_uw:       /* unwind for pret */
        goto Pret_uw;

```

```

        case A_Pfail_uw:          /* unwind for pfail */
            goto Pfail_uw;
    }
    sp = (word *)rargp + 1;    /* set sp to result */
    continue;
}

```

Thus, when `interp()` returns to a C function with an unwinding signal, there is a cascade of C returns until `ilevel` is the same as it was when the current expression frame was created. Note that there are several cases in addition to `unmark` where unwinding is necessary.

## 9.4 Generative Control Structures

In addition to functions and operators that may generate more than one result, there are several generative control structures at the level of virtual machine instructions.

### 9.4.1 Alternation

The virtual machine instructions for

*expr<sub>2</sub> | expr<sub>3</sub>*

are

```

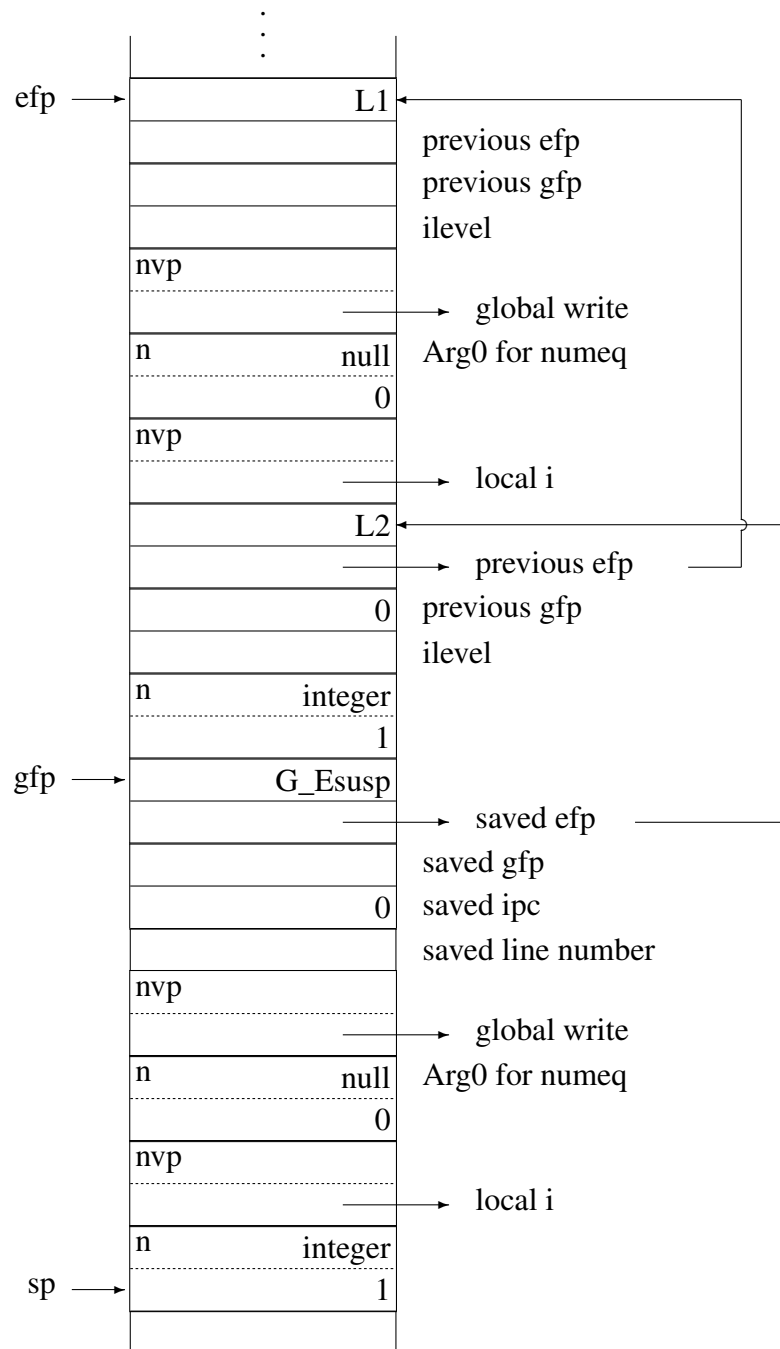

mark      L1
code for expr2
esusp
goto      L2
L1:
code for expr3
L2:

```

The `mark` instruction creates an expression frame marker for alternation whose purpose is to preserve the failure `ipc` for `L1` in case the results for *expr<sub>3</sub>* are needed. If *expr<sub>2</sub>* produces a result, `esusp` creates a generator frame with the usual marker and then copies the portion of the interpreter stack between the last expression or generator frame marker and the alternation marker to the top of the stack. It then pushes a copy of the result produced by *expr<sub>2</sub>*. This connects the result produced by *expr<sub>2</sub>* with the expression prior to the alternation control structure. Next, `esusp` sets `efp` to point to the expression frame marker prior to the alternation marker. For example, in the expression

`write(i := 1 | 2)`

the stack after the execution of `esusp` is

The top portion of the stack is the same as if `expr2` had produced a result in the absence of alternation. However, the generator frame marker pushed by `esusp` contains a pointer to the alternation marker.

If another result from *expr2* is needed, the generator frame left by *esusp* is removed, restoring the stack to its state when *expr2* produced a result. If *expr2* itself was a generator that suspended, it is resumed. Otherwise, control is transferred to *efail* and *ipc* is set to a value corresponding to L1, so that *expr3* is evaluated next.

### 9.4.2 Repeated Alternation

Alternation is the general model for generative control structures. Repeated alternation, *|expr*, is similar to alternation, and would be equivalent to

*expr | expr | expr | ...*

except for a special termination condition that causes repeated alternation to stop if *expr* does not produce a result. Without this termination condition, an expression such as

*|upto(c, s)*

would never return if *upto()* failed—expression evaluation would vanish into a "black hole." Expressions that produce results at one time but not at another also are useful. For example,

*|read()*

generates the lines from the standard input file. Because of the termination condition, this expression terminates when the end of the input file is reached. If it vanished into a "black hole," it could not be used safely.

If it were not for the termination condition, the virtual machine instructions for *|expr* would be

```
L1:
    mark          L1
    code for expr
    esusp
```

The "black hole" here is evident—if *expr* fails, it is evaluated again and there is no way out.

The termination condition is handled by an instruction that changes the failure *ipc* in the current expression marker. The actual virtual machine instructions for *|expr* are

```
L1:
    mark0
    code for expr
    chfail        L1
    esusp
```

The virtual machine instruction `mark0` pushes an expression frame marker with a zero failure ipc. If a zero failure ipc is encountered during failure, as illustrated by the code for `efail` in Sec. 9.3, failure is transmitted to the enclosing expression. If *expr* produces a result, however, the `chfail` instruction is executed. It changes the failure ipc in the current expression marker to correspond to L1, so that if *expr* does not produce a result when it is resumed, execution starts at the location in the icode corresponding to L1 again, causing another iteration of the alternation loop. It is important to realize that `chfail` only changes the failure ipc in the current expression marker on the stack. Subsequent execution of `mark0` creates a new expression frame whose marker has a zero failure ipc.

### 9.4.3 Limitation

In the limitation control structure,

*expr1* \ *expr2*

the normal left-to-right evaluation of Icon is reversed and *expr2* is evaluated first. The virtual machine instructions are

*code for expr2*

limit

*code for expr1*

lsusp

If *expr2* succeeds, its result is on the top of the stack. The `limit` instruction checks this result to be sure that it is legal—an integer greater than or equal to zero. If it is not an integer, an attempt is made to convert it to one. If the limit value is zero, `limit` fails. Otherwise, `limit` creates an expression frame marker with a zero failure ipc and execution continues, so that *expr1* is evaluated in its own expression frame. During the evaluation of *expr1*, the limit value is directly below its expression marker. For example, in

*expr1* \ 10

the stack prior to the evaluation of *expr1* is

If *expr1* produces a result, `lsusp` is executed. The `lsusp` instruction is very similar to `esusp`. Before producing a generator frame, however, `lsusp` decrements the limit value. If it becomes zero,

the expression frame for *expr1* is removed, the C stack is unwound, and the last value it produced is placed on the stack in place of the limit value. Otherwise, it copies the portion of the interpreter stack between the end of the last expression or generator frame marker and the limit value to the top of the stack. Note that no generator frame is needed.

## 9.5 Iteration

The difference between evaluation and resumption in a loop is illustrated by the virtual machine instructions for a conventional loop

*while expr1 do expr2*

and the iteration control structure

*every expr1 do expr2*

The instructions for while-do are

```
L1:
  mark0
  code for expr1
  unmark
  mark    L1
  code for expr2
  unmark
  goto    L1
```

If *expr1* fails, the entire expression fails and failure is transmitted to the enclosing expression frame because the failure ipc is zero. If *expr1* produces a result, *expr2* is evaluated in a separate expression frame. Whether *expr2* produces a result or not, its expression frame is removed and execution continues at the beginning of the loop.

The instructions for every-do are

```
mark0
code for expr1
pop
mark0
code for expr2
unmark
efail
```

If *expr1* fails, the entire expression fails and failure is transmitted to the enclosing expression frame as in the case of *while-do*. If *expr1* produces a result, it is discarded by the *pop* instruction, since this result is not used in any subsequent computation. The expression frame for *expr1* is not removed, however, and *expr2* is evaluated in its own expression frame within the expression frame for *expr1* (unlike the case for the *while* loop). If *expr2* produces a result, its expression frame is removed and *efail* is executed. If *expr2* fails, it transmits failure to the enclosing expression frame, which is the expression frame for *expr1*. If *expr2* produces a result, *efail* causes failure in the expression frame for *expr1*. Thus, the effect is the same, whether or not *expr2* produces a result. All results are produced simply by forcing failure.

If the expression frame for *expr1* contains a generator frame, which is the case if *expr1* suspended, evaluation is resumed accordingly, so that *expr1* can produce another result. If *expr1* simply produces a result instead of suspending, there is no generator frame, *efail* removes its expression frame, and failure is transmitted to the enclosing expression frame.

## 9.6 String Scanning

String scanning is one of the most useful operations in Icon. Its implementation, however, is comparatively simple. There is no special expression-evaluation mechanism associated with string scanning *per se*; all "pattern matching" follows naturally from goal-directed evaluation.

The string-scanning keywords, *&subject* and *&pos* must be handled properly, however. These keywords have global scope with respect to procedure invocation, but they are maintained in a stack-like fashion with respect to string-scanning expressions.

The expression

*expr1 ? expr2*

is a control structure, not an operation, since, by definition, the arguments for an operation are evaluated before the operation is performed. This form of evaluation does not work for string scanning, since after *expr1* is evaluated, but before *expr2* is evaluated, the previous values of *&subject* and *&pos* must be saved and new ones established. Furthermore, when string scanning is finished, the old values of *&subject* and *&pos* must be restored. In addition, if string scanning succeeds, the values of these keywords at the time string scanning produces a result must be saved so that they can be restored if the string-scanning operation is resumed to produce another result.

The virtual machine instructions for

*expr1 ? expr2*

are

```

code for expr1
bscan
code for expr2
escan

```

If *expr1* succeeds, it leaves a result on the top of the stack. The `bscan` instruction assures that this value is a string, performing a conversion if necessary. Otherwise, the old values of `&subject` and `&pos` are pushed on the stack, the value of `&subject` is set to the (possibly converted) one produced by *expr1*, and `&pos` is set to 1.

The `bscan` instruction then suspends. This is necessary in case *expr2* fails, so that `bscan` can get control again to perform data backtracking, restoring the previous values of `&subject` and `&pos` from the stack where they were saved.

If *expr2* succeeds, the `escan` instruction copies the descriptor on the top of the stack to its Arg0 position, overwriting the result produced by *expr2*. It then exchanges the current values of `&subject` and `&pos` with those saved by `bscan` thus restoring the values of these keywords to their values prior to the scanning expression and at the same time saving the values they had at the time *expr2* produced a result. The `escan` instruction then suspends.

If `escan` is resumed, the values of `&subject` and `&pos` are restored from the stack, restoring the situation to what it was when *expr2* produced a result. The `escan` instruction then fails in order to force the resumption of any suspended generators left by *expr2*.

Suppose, for example, that the values of `&subject` and `&pos` are "the" and 2 respectively, when the following expression is evaluated:

```
read(f) ? move(4)
```

Suppose `read(f)` produces the string "coconuts". The stack is

```

&subject:  "the"
&pos:      2

```

The `bscan` instruction is executed, pushing the current values of `&subject` and `&pos`:

&subject: "the"  
&pos: 2

The `bscan` instruction sets `&subject` to "coconuts" and `&pos` to 1. The `bscan` instruction then suspends and `move(4)` is evaluated. It suspends, and the top of the stack is

&subject: "coconuts"  
&pos: 5

The `escan` instruction is executed next. It copies the descriptor on the top of the stack to replace the result produced by `expr2`. It then exchanges the current values of `&subject` and `&pos` with those on the stack:

```

&subject:  "the"
&pos      : 2

```

The `escan` instruction then suspends, building a generator frame. The result of `expr2` is placed on the top of the stack, becoming the result of the entire scanning expression.

Since `escan` suspends, the saved values of `&subject` and `&pos` are preserved in a generator frame on the stack until `escan` is resumed or until the current expression frame is removed.

RETROSPECTIVE: The implementation of expression evaluation in Icon focuses on the concept of an expression frame within which control backtracking can occur. Bounded expressions, for example, are represented on the stack by expression frames, which confine backtracking.

In the absence of generators, failure simply results in the removal of the current expression frame and transfer to a new location in the icode, bypassing instructions that otherwise would have been executed.

State information must be saved when a generator suspends, so that its evaluation can be resumed. This information is preserved in a generator frame within the current expression frame. Generator frames are linked together in a last-in, first-out fashion. Goal-directed evaluation is a natural consequence of resuming the most recently suspended generator when an expression fails, instead of simply removing the current expression frame.

String scanning involves saving and restoring the values of `&subject` and `&pos`. This is somewhat complicated, since scanning expressions can suspend and be resumed, but string scanning itself introduces nothing new into expression evaluation: generators and goal-directed evaluation provide "pattern matching."

## EXERCISES

**9.1** Circle all the bounded expressions in the following segments of code:

```

while line := read() do
    if *line = i then write(line)

if (i = find(s1,s2)) & (j = find(s1,s3)) then {
    write(i)
    write(j)
}

```

```

line ? while write(move(1)) do
      move(1)

```

**9.2** Describe the effect of nested generators and generators in mutual evaluation on the interpreter level.

**9.3** Consider a hypothetical control structure called *exclusive alternation* that is the same as regular alternation, except that if the first argument produces at least one result, the results from the second argument are not produced. Show the virtual machine instructions that should be generated for exclusive alternation.

**9.4** The expression `read(f)` is an example of an expression that may produce result at one time and fail at another. This is possible because of a side effect of evaluating it—changing the position in the file `f`. Give an example of an expression that may fail at one time and produce a result at a subsequent time.

**9.5** There are potential “black holes” in the expression-evaluation mechanism of Icon, despite the termination condition for repeated alternation. Give an example of one.

**9.6** The expression frame marker produced by `limit` makes it easy to locate the limitation counter. Show how the counter could be located without the marker.

**9.7** Suppose that the virtual machine instructions for

```

every expr1 do expr2

```

did not pop the result produced by *expr1*. What effect would this have?

**9.8** The virtual machine instructions for

```

every expr

```

are

```

mark0

```

```

code for expr

```

```

pop

```

```

efail

```

so that failure causes *expr* to be resumed. The keyword `&fail` also fails, so that the virtual machine instructions for

```

expr & &fail

```

are

*code for expr*  
 efail

It is sometimes claimed that these two expressions are equivalent. If this were so, the shorter virtual machine instruction sequence for the second expression could be used for the first expression. Explain why the two expressions are not equivalent, in general, and give an example in which they are different.

**9.9** Diagram the states of the stack for the example given in Sec. 9.6, showing all generator frames.

**9.10** Show the successive stack states for the evaluation of the following expressions, assuming that the values of &subject and &pos are "the" and 2 respectively, and that read() produces "coconuts" in each case:

- (a) read(f) ? move(10)
- (b) (read(f) ? move(4)) ? move(2)
- (c) read(f) ? (move(4) ? move(2))
- (d) (read(f) ? move(4)) ? move(10)
- (e) (read(f) ? move(4 | 6)) ? move(5)
- (f) (read(f) ? move(4)) & (read(f) & move(10))

**9.11** Write Icon procedures to emulate string scanning. *Hint:* consider the virtual machine instructions for

*expr1 ? expr2*

# Chapter 10

## Functions, Procedures, and Co-Expressions

PERSPECTIVE: The invocation of functions and procedures is central to the evaluation of expressions in most programming languages. In Icon, this activity has several aspects that complicate its implementation. Functions and procedures are data values that can be assigned to identifiers, passed as arguments, and so on. Consequently, the meaning of an invocation expression cannot be determined until it is evaluated. Functions and procedures can be called with more or fewer arguments than expected. Thus, there must be a provision for adjusting argument lists at run time. Since mutual evaluation has the same syntax as function and procedure invocation, run-time processing of such expressions is further complicated.

Co-expressions, which require separate stacks for their evaluation, add complexities and dependencies on computer architecture that are not found elsewhere in the implementation.

### 10.1 Invocation Expressions

As mentioned in Sec. 8.2.4, the virtual machine code for an expression such as

*expr0(expr1, expr2, ..., exprn)*

is

```
code for expr0
code for expr1
code for expr2
...
code for exprn
invoke n
```

Consequently, the stack when the invoke instruction is executed is

The meaning of the expression, and hence the action taken by `invoke`, depends on the result produced by  $expr_0$ . If the value of  $expr_0$  is an integer or convertible to an integer, the invocation expression corresponds to mutual evaluation. If this integer is negative, it is converted to the corresponding positive value with respect to the number of arguments. If the value is between one and  $n$ , the corresponding descriptor is copied on top of the result of  $expr_0$ , `sp` is set to this position, and `invoke` transfers control to the beginning of the interpretive loop. On the other hand, if the value is out of range, `invoke` fails. Note that the returned value overwrites the descriptor for  $expr_0$ , whereas for operators a null-valued descriptor is pushed to receive the value.

If the value of  $expr_0$  is a function or a procedure, the corresponding function or procedure must be invoked with the appropriate arguments. A function or procedure value is represented by a descriptor that points to a block that contains information about the function or procedure.

## 10.2 Procedure Blocks

Functions and procedures have similar blocks, and there is no source-language type distinction between them.

**Blocks for Procedures.** Blocks for procedures are constructed by the linker, using information provided by the translator. Such blocks are read in as part of the icode file when an Icon program is executed. The block for a procedure contains the usual title and size words, followed by six words that characterize the procedure:

- (1) The icode location of the first virtual machine instruction for the procedure.
- (2) The number of arguments expected by the procedure.

- (3) The number of local identifiers in the procedure.
- (4) The number of static identifiers in the procedure.
- (5) The index in the static identifier array of the first static identifier in the procedure.
- (6) A C string for the name of the file in which the procedure declaration occurred.

The remainder of the procedure block contains qualifiers: one for the string name of the procedure, then others for the string names of the arguments, local identifiers, and static identifiers, in that order.

For example, the procedure declaration

```

procedure calc(i,j)
  local k
  static base, index
      :
end

```

has the following procedure block:

proc	
80	size of block
—	→ initial ipc
2	number of arguments
1	number of local identifiers
2	number of static identifiers
0	index of first static identifier
—	→ file name
4	
—	→ "calc"
1	
—	→ "i"
1	
—	→ "j"
1	
—	→ "k"
4	
—	→ "base"
5	
—	→ "index"

The 0 value for the index in the static identifier array indicates that base is the first static identifier in the program. The indices of static identifiers are zero-based and increase throughout a program as static declarations occur.

**Blocks for Functions.** Blocks for functions are created by the macro FncDcl that occurs at the beginning of every C function that implements an Icon function. Such blocks for functions are similar to those for procedures but are distinguished by the value -1 in the word that otherwise contains the number of local identifiers. The entry point is the entry point of the C routine for the function. The procedure block for `repl` is typical:

proc	
40	size of block
—	→ C entry point
2	number of arguments
-1	function indicator
0	not used
0	not used
0	not used
4	
—	→ "repl"

Note that there are no argument names.

Some functions, such as `write()`, allow an arbitrary number of arguments. This is indicated by the value -1 in place of the number of arguments:

proc	
40	size of block
—	→ C entry point
-1	indicator of a variable number of arguments
-1	function indicator
0	not used
0	not used
0	not used
5	
—	→ "write"

## 10.3 Invocation

### 10.3.1 Argument Processing

Argument processing begins by dereferencing the arguments in place on the stack. If a fixed number of arguments is specified in the procedure block, this number is compared with the argument of invoke, which is the number of arguments on the stack.

If there are too many arguments, `sp` is set to point to the last one expected. For example, the expression

`numeric(i, j)`

results in

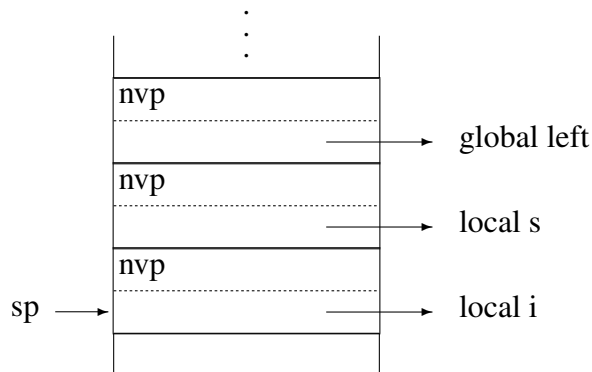

Since `numeric()` expects only one argument, `sp` is reset, effectively popping the second argument:

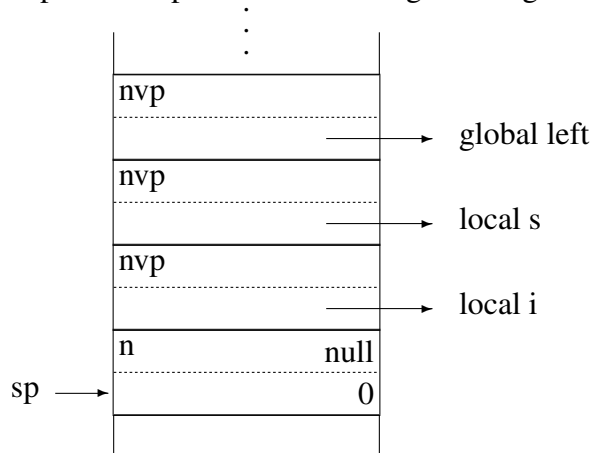

On the other hand, if there are not enough arguments, null-valued descriptors pushed to supply the missing arguments. For example, the expression

`left(s, i)`

results in

and a null value is pushed to provide the missing third argument:

### 10.3.2 Function Invocation

Function invocation involves calling a C function in a fashion that is very similar to evaluating an operator. In the case of an Icon function, the entry point of the corresponding C function is obtained from the procedure block rather than by indexing an array of function pointers corresponding to operator codes.

For an Icon function that has a fixed number of arguments, the C function is called with a single argument that is a pointer to the location of Arg0 on the interpreter stack. Note that Arg0 is the descriptor that points to the procedure block. For an Icon function that may be called with an arbitrary number of arguments, the C function is called with two arguments: the number of arguments on the stack and a pointer to Arg0.

Like an operator, a function may fail, return a result, or suspend. The coding protocol is the same as for operators. The function find is an example:

```
function{*} find(s1,s2,i,j)
  str_anal( s2, i, j )
  if !cnv:string(s1) then
```

```

        runerr(103,s1)
    body {
        register char *str1, *str2;
        C_integer s1_len, l, term;

        /*
         * Loop through s2[i:j] trying to find s1 at each point,
         * stopping when the remaining portion s2[i:j] is too short
         * to contain s1. Optimize me!
         */
        s1_len = StrLen(s1);
        term = cnv_j - s1_len;
        while (cnv_i <= term) {
            str1 = StrLoc(s1);
            str2 = StrLoc(s2) + cnv_i - 1;
            l = s1_len;

            /*
             * Compare strings on a byte-wise basis; if the end is
             * reached before inequality is found, suspend with the
             * position of the string.
             */
            do {
                if (l-- <= 0) {
                    suspend C_integer cnv_i;
                    break;
                }
            } while (*str1++ == *str2++);
            cnv_i++;
        }
        fail;
    }
end

```

str\_anal() is an RTL multi-line macro for performing the standard conversions and defaulting for string analysis functions. It takes as arguments the parameters for subject, beginning position, and ending position. It produces declarations for these 3 names prepended with cnv\_. These variables will contain the converted versions of the arguments.

```
#bifdef str_anal(s, i, j)
```

```

declare {
    C_integer cnv_ ## i;
    C_integer cnv_ ## j;
}

abstract {
    return integer
}

if is:null(s) then {
    inline {
        s = k_subject;
    }
    if is:null(i) then inline {
        cnv_ ## i = k_pos;
    }
}
else {
    if !cnv:string(s) then
        runerr(103,s)
    if is:null(i) then inline {
        cnv_ ## i = 1;
    }
}

if !is:null(i) then
    if cnv:C_integer(i,cnv_ ## i) then inline {
        if ((cnv_ ## i = cvpos(cnv_ ## i, StrLen(s))) == CvtFail)
            fail;
    }
    else
        runerr(101,i)

if is:null(j) then inline {
    cnv_ ## j = StrLen(s) + 1;
}
else if cnv:C_integer(j,cnv_ ## j) then inline {
    if ((cnv_ ## j = cvpos(cnv_ ## j, StrLen(s))) == CvtFail)
        fail;
}

```

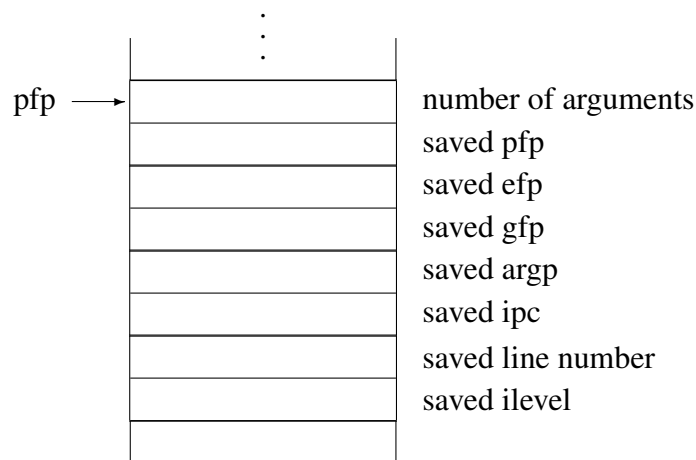

```

    if (cnv_ ## i > cnv_ ## j) {
        register C_integer tmp;
        tmp = cnv_ ## i;
        cnv_ ## i = cnv_ ## j;
        cnv_ ## j = tmp;
    }
}
else
    runerr(101,j)
#endif

```

### 10.3.3 Procedure Invocation

In the case of procedure invocation, a *procedure frame* is pushed onto the interpreter stack to preserve information that may be changed during the execution of the procedure and that must be restored when the procedure returns. As for other types of frames, a procedure frame begins with a marker. A procedure frame marker consists of eight words:

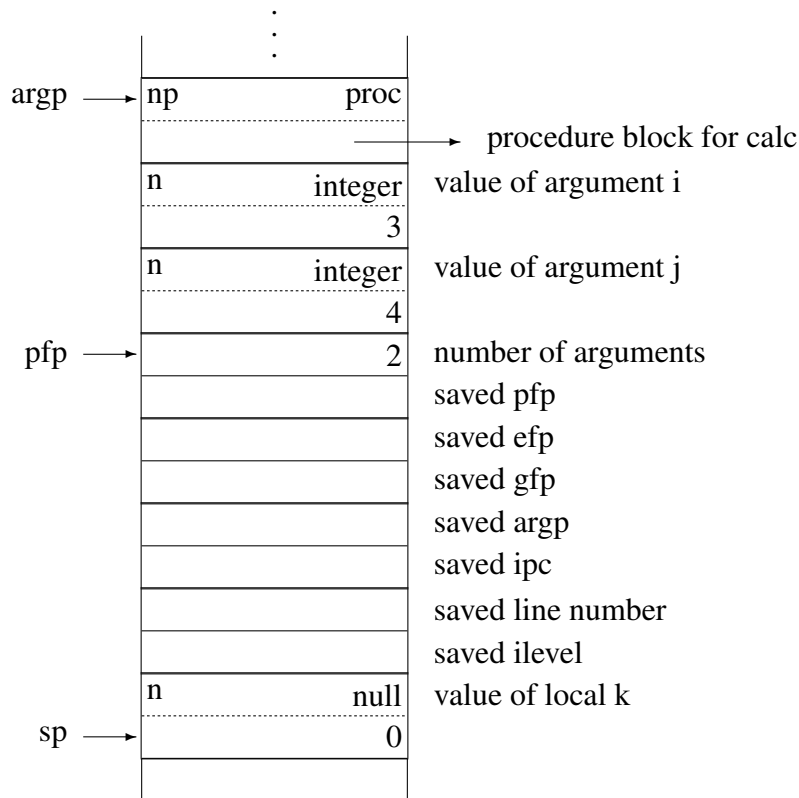

The current procedure frame is pointed to by pfp, and argp points to the place on the interpreter stack where the arguments begin, analogous to Arg0 for functions. The number of arguments, which can be computed from pfp and argp, is provided to make computations related to arguments more convenient.

After the procedure marker is constructed, a null-valued descriptor is pushed for each local identifier. For example, the call

calc(3,4)

for the procedure declaration given in Sec. 10.2 produces

Once the null values for the local identifiers are pushed, ipc is set to the entry point given in the procedure block and efp and gfp are set to zero. Execution then continues in the interpreter with the new ipc.

The three forms of return from a procedure are the same as those from a function and correspond to the source-language expressions

```
return e
fail
suspend e
```

The corresponding virtual machine instructions are pret, pfail, and psusp. For example, the virtual machine code for

```
return &null
```

is

```
pnull
pret
```

In the case of pret, the result currently on the top of the interpreter stack is copied on top of the descriptor pointed to by argp. If this result is a variable that is on the stack (and hence local to the

current procedure call), it is dereferenced in place. The C stack is unwound, since there may be suspended generators at the time of the return. The values saved in the procedure frame marker are restored, and execution continues in the interpreter with the restored ipc.

In the case of failure, the C stack is unwound as it is for `pret`, values are restored from the procedure frame marker, and control is transferred to `efail`.

Procedure suspension is similar to other forms of suspension. The descriptor on the top of the interpreter stack is dereferenced, if necessary, and saved. A generator frame marker is constructed on the interpreter stack to preserve values that may be needed if the procedure call is resumed. For procedure suspension, a generator frame marker contains two words in addition to those needed for other kinds of generator frame markers and has the form

⋮	
G_Psusp	generator type
	saved efp
	saved gfp
	saved ipc
	saved line number
	saved pfp
	saved argp

After the generator frame marker is pushed, the portion of the stack between the last generator or expression frame marker before the call to this procedure and the word prior to `argp` is copied to the top of the stack. Finally, the saved descriptor, which is the result produced by the procedure, is pushed on the top of the stack. Execution then continues in the interpreter with the restored ipc.

## 10.4 Co-Expressions

Co-expressions add another dimension to expression evaluation in Icon. The important thing to understand about co-expressions is that Icon evaluation is always in *some* co-expression. Although it is not evident, the execution of an Icon program begins in a co-expression, namely the value of `&main`.

A co-expression requires both an interpreter stack and a C stack. In the co-expression for `&main`, the interpreter stack is statically allocated and the C stack is the one normally used for C execution—the "system stack" on some computers. The creation of a new co-expression produces a new interpreter stack and a new C stack, as well as space that is needed to save state information. When a co-expression is activated, the context for evaluation is changed to the stacks for the activated co-expression. When the activation of a co-expression produces a result, it in turn activates the co-expression that activated it, leaving the stacks from which the return occurred in a state

of suspension. Thus, co-expression activation constitutes a simple context switch. In every co-expression, expression evaluation is in some state, possibly actively executing, possibly suspended, or possibly complete and unreachable.

The virtual machine instructions for

create *expr*<sub>0</sub>

are

```

      goto          L3
L1:   pop
      mark          L2
      code for expr0
      coret
      efail
L2:   cofail
      goto          L2
L3:   create        L1

```

Control goes immediately to L3, where the instruction create constructs a co-expression block and returns a descriptor that points to it. This block contains space for i-state variables, space for the state of the C stack, an interpreter stack, and a C stack.

The code between L1 and L3 is not executed until the co-expression is activated. The pop instruction following L1 discards the result transmitted to a co-expression on its first activation, since there is no expression waiting to receive the result of an initial activation. Next, an expression frame marker is created, and the code for *expr*<sub>0</sub> is executed. If *expr*<sub>0</sub> produces a result, coret is executed to return the result to the activating expression. If the co-expression is activated again, its execution continues with efail, which causes any suspended generators in the code for *expr*<sub>0</sub> to be resumed. If *expr*<sub>0</sub> fails, the expression frame is removed and cofail is executed. The cofail instruction is very similar to the coret instruction, except that it signals failure rather than producing a result. Note that if a co-expression that returns by means of cofail is activated again, the cofail instruction is executed in a loop.

A co-expression is activated by the expression

*expr*<sub>1</sub> @ *expr*<sub>2</sub>

for which the virtual machine code is

```

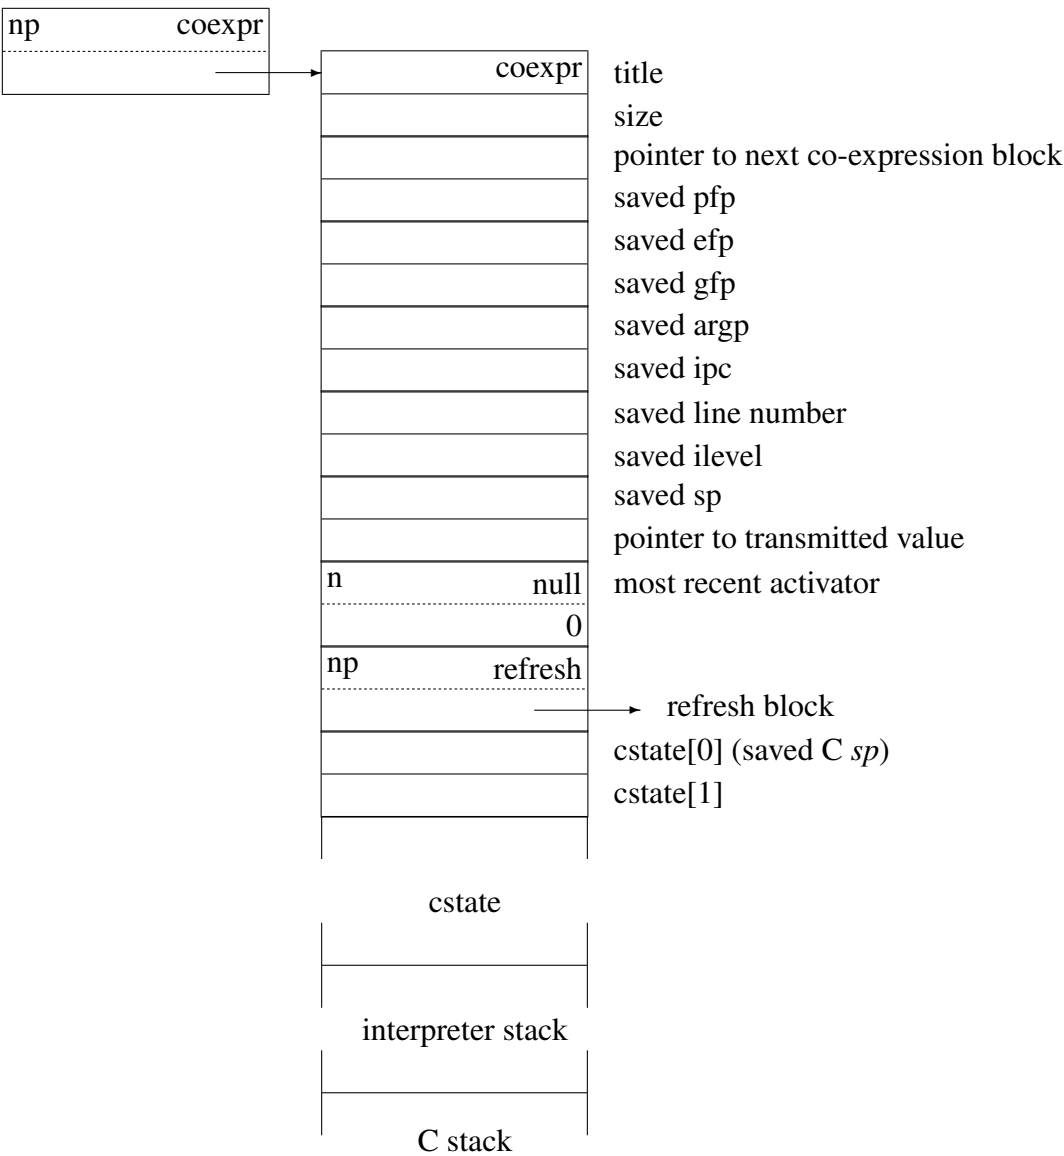

code for expr1
code for expr2
coact

```

The more common form of activation,  $@expr_0$ , is just an abbreviation for  $\&\text{null } @ expr_0$ ; a result is always transmitted, even if it is the null value.

The virtual machine code for  $expr_1$  produces the descriptor for the result that is to be transmitted to the co-expression being activated. The `coact` instruction dereferences the result produced by  $expr_2$ , if necessary, and checks to make sure it is a co-expression. After setting up state information, `coact` transfers control to the new co-expression with `ipc` set to L1. Execution continues there. If `coret` is reached, control is restored to the activating co-expression. The instructions `coact` and `coret` are very similar. Each saves the current co-expression state, sets up the new co-expression state, and transfers control.

**Co-Expression Blocks.** There is quite a bit of information associated with a co-expression, and space is provided for it in a co-expression block:

The interpreter stack and C stack shown in this diagram are not to scale compared with the rest of the block. Both are comparatively large; the actual sizes depend on the address space of the target computer.

The first word of the block is the usual title. The next word contains the number of results the co-expression has produced-its "size." Then there is a pointer to the next co-expression block on a list that is maintained for garbage collection purposes. See Sec. 11.3.4. Following this pointer there are i-state variables: pfp, efp, gfp, argp, ipc, sp, the current program line number, and ilevel.

Then there is a descriptor for the transmitted result, followed by two more descriptors: one for the co-expression that activates this one and one for a *refresh* block that is needed if a copy of this co-expression block is needed. C state information is contained in an array of words, cstate, for registers and possibly other state information. The array cstate typically contains fifteen words

for such information. The C *sp* is stored in `cstate[0]`. The use of the rest of `cstate` is machine-dependent.

Finally, there is an interpreter stack and a C stack. On a computer with a downward-growing C stack, such as the VAX, the base of the C stack is at the end of the co-expression block and the interpreter and C stacks grow toward each other. On a computer with an upward-growing C stack, the C stack base follows the end of the interpreter stack.

**Stack Initialization.** When a co-expression is first activated, its interpreter stack must be in an appropriate state. This initialization is done when the co-expression block is created. A procedure frame, which is a copy of the procedure frame for the procedure in which the `create` instruction is executed, is placed on the new stack. It consists of the words from `argp` through the procedure frame marker and the descriptors for the local identifiers. The `efp` and `gfp` in the co-expression block are set to zero and the `ipc` is set to the value given in the argument to the `create` instruction (L1).

No C state is set up on the new C stack; this is handled when the co-expression is activated the first time. The initial null value for the activator indicates the absence of a valid C state.

**Co-Expression Activation.** As mentioned previously, `coact` and `coret` perform many similar functions—both save current state information, establish new state information, and activate another co-expression. The current i-state variables are saved in the current co-expression block, and new ones are established from the co-expression block for the co-expression being activated. Similar actions are taken for the C state. Since the C state is machine-dependent, the "context switch" for the C state is performed by a routine, called `coswitch()`, that contains assembly-language code.

The C state typically consists of registers that are used to address the C stack and registers that must be preserved across the call of a C function. On the VAX, for example, the C stack registers are *sp*, *ap*, and *fp*. Only the registers `r6` through `r11` must be saved for some C compilers, while other C compilers require that `r3` through `r11` be saved. Once the necessary registers are saved in the `cstate` array of the current co-expression, new values of these registers are established. If the co-expression being activated has been activated before, the C state is set up from its `cstate` array, and `coswitch()` returns to `interp()`. At this point, execution continues in the newly activated co-expression. Control is transferred to the beginning of the interpreter loop, and the next instruction (from the `ipc` for the co-expression) is fetched.

However, when a co-expression is activated for the first time, there are no register values to restore, since no C function has yet been called for the new co-expression. This is indicated, as mentioned previously, by a null activator, which is communicated to `coswitch()` by an integer argument. In this case, `coswitch()` sets up registers for the call of a C function and calls `interp()` to start the execution of the new co-expression. Such a call to `interp()` on the first activation of a co-expression corresponds to the call to `interp()` that starts program execution in the co-expression `&main` for the main procedure. There can never be a return from the call to `interp()` made in `coswitch()`, since program execution can only terminate normally by a return from the main procedure, in `&main`.

The function `coswitch()` is fastest if it is machine-dependent. The version for the x86 with the

GCC compiler is an example:

```

coswitch:
    pushl %ebp
    movl %esp,%ebp
    movl 8(%ebp),%eax
    movl %esp,0(%eax)
    movl %ebp,4(%eax)
    movl 12(%ebp),%eax
    cmpl $0,16(%ebp)
    movl 0(%eax),%esp
    je    .L2

    movl 4(%eax),%ebp
    jmp   .L1

.L2:
    movl $0,%ebp
    pushl $0
    pushl $0
    call  new_context
    pushl $.LC0
    call  syserr
    addl $12,%esp

.L1:
    leave
    ret

```

If no assembler co-expression switch is available, modern platforms with POSIX threads can use Icon 9.5.1's supported form of co-expressions, which is more than 100x slower and approximately twice as many lines of C. The public interface in either case looks like:

```
int coswitch(void *old_cs, void *new_cs, int first);
```

The variables `old_cs` and `new_cs` are pointers to the `cstate` arrays for the activating and activated co-expressions, respectively. The value of `first` is 0 if the co-expression is being activated for the first time. Note that in order to write `coswitch()` it is necessary to know how the first two arguments are accessed in assembly language. For the previous example, `old_cs` and `new_cs` are eight and twelve bytes from the `ebp` register, respectively.

**Refreshing a Co-Expression.** The operation  $\hat{expr}_0$  creates a copy of the co-expression produced by  $expr_0$  with its state initialized to what it was when it was originally created. The refresh block for  $expr_0$  contains the information necessary to reproduce the initial state. The refresh block contains the original ipc for the co-expression, the number of local identifiers for the procedure in which  $expr_0$  was created, a copy of the procedure frame marker at the time of creation, and the values of the arguments and local identifiers at the time of creation. Consider, for example,

```

procedure labgen(s)
  local i, j, e
  i := 1
  j := 100
  e := create (s || (i to j) || ":")
end

```

For the call `labgen("L")`, the refresh block for `e` is

	refresh	title
	88	size of block
		initial ipc
	3	number of local identifiers
		saved number of arguments
		saved pfp
		saved efp
		saved gfp
		saved argp
		saved ipc
		saved line number
		saved ilevel
n	proc	value of labgen
		→ procedure block
	1	value of s
		→ "L"
n	null	value of i
	1	
n	integer	value of j
	100	
n	null	value of e
	0	

RETROSPECTIVE: Invocation expressions are more complicated to implement than operators, since the meaning of an invocation expression is not known until it is evaluated. Since functions and procedures are source-language values, the information associated with them is stored in blocks in the same manner as for other types.

The C code that implements Icon functions is written in the same fashion as the code for operators. Procedures have source-language analogs of the failure and suspension mechanisms used for implementing functions and operators. Procedure frames identify the portions of the interpreter stack associated with the procedures currently invoked.

A co-expression allows an expression to be evaluated outside its lexical site in the program by providing separate stacks for its evaluation. The possibility of multiple stacks in various states of evaluation introduces technical problems in the implementation, including a machine-dependent context switch.

## EXERCISES

**10.1** What happens if a call of a procedure or function contains an extra argument expression, but the evaluation of that expression fails?

**10.2** Sometimes it is useful to be able to specify a function or procedure by means of its string name. Icon supports "string invocation," which allows the value of  $expr_0$  in

$$expr_0(expr_1, expr_2, \dots, expr_n)$$

to be a string. Thus,

"write"(s)

produces the same result as

write(s)

Of course, such a string name is usually computed, as in

(read())(s)

Describe what is involved in implementing this aspect of invocation. Operators also may be invoked by their string names, as in

"+"(i,j)

What is needed in the implementation to support this facility? Can a control structure be invoked by a string name?

**10.3** If the result returned by a procedure is a variable, it may need to be dereferenced. This is done in the code for `pret` and `psusp`. For example, if the result being returned is a local identifier, it must be replaced by its value. What other kinds of variables must be dereferenced? Is there any difference in the dereferencing done by `pret` and `psusp`?

**10.4** How is the structure of a co-expression block different on a computer with an upward-growing C stack compared to one with a downward-growing C stack? What is the difference between the two cases in terms of potential storage fragmentation?

# Chapter 11

## Storage Management

Editorial Note: the implementation of storage management has transformed over time as computer hardware capabilities have changed. Despite this, the main principles of Icon and Unicon’s garbage collector are unmodified after several decades.

PERSPECTIVE: The implementation of storage management must accommodate a wide range of allocation requirements. At the same time, the implementation must provide generality and some compromise between “normal” programs and those that have unusual requirements. Although it is clearly sensible to satisfy the needs of most programs in an efficient manner, there is no way to define what is typical or to predict how programming style and applications may change. Indeed, the performance of the implementation may affect both programming style and applications.

Strings and blocks can be created during program execution at times that cannot be predicted, in general, from examination of the text of a program. The sizes of strings and of some types of blocks may vary and may be arbitrarily large, although practical considerations dictate some limits. There may be an arbitrary number of strings and blocks. The “lifetimes” during which they may be used are arbitrary and are unrelated, in general, to procedure calls and returns.

Different programs vary considerably in the number, type, and sizes of data objects that are created at run time. Some programs read in strings, transform them, and write them out without ever creating other types of objects. Other programs create and manipulate many lists, sets, and tables but use few strings. Relatively few programs use co-expressions, but there are applications in which large numbers of co-expressions are created.

Since a program can construct an arbitrary number of data objects of arbitrary sizes and lifetimes, some mechanism is needed to allow the reuse of space for “dead” objects that are no longer accessible to the program. Thus, in addition to a mechanism for allocating storage for objects at run time, there must be a storage-reclamation mechanism, which usually is called *garbage collection*. The methods used for allocation and garbage collection are interdependent. Simple and fast allocation methods usually require complex and time-consuming garbage-collection techniques, while more efficient garbage-collection techniques generally lead to more complex allocation techniques.

Storage management has influences that are far-reaching. In some programs, it may account for a major portion of execution time. The design of data structures, the layout of blocks, and the representation of strings are all influenced by storage-management considerations. For example, both a descriptor that points to a block and the first word of the block contain the same type code. This information is redundant as far as program execution is concerned, since blocks are accessed only via descriptors that point to them. The redundant type information is motivated by storage-management considerations. During garbage collection, it is necessary to access blocks directly, rather than through pointers from descriptors, and it must be possible to determine the type of a block from the block itself. Similarly, the size of a block is of no interest in performing language operations, but the size is needed during garbage collection. Blocks, therefore, carry some “overhead” for storage management. This overhead consists primarily of extra space, reflecting the fact that it takes more space to manage storage dynamically than would be needed if space were allocated statically. Balancing space overhead against efficiency in allocating and collecting objects is a complex task.

Such problems have plagued and intrigued implementors since the early days of LISP. Many ways have been devised to handle dynamic storage management, and some techniques have been highly refined to meet specific requirements (Cohen 1981). In the case of Icon, there is *more* emphasis on storage management for strings than there is in a language, such as LISP, where lists predominate. Icon’s storage-management system reflects previous experience with storage-management systems used in XPL (McKeeman, Horning, and Wortman 1970), SNOBOL4 (Hanson 1977), and the earlier Ratfor implementation of Icon (Hanson 1980). The result is, of course, somewhat idiosyncratic, but it provides an interesting case study of a real storage-management system.

### **A brief history of Icon’s storage management**

The main changes in the overall approach to storage management since version 6 have been in the treatment of the Allocated Storage areas, which is discussed in section 11.1 below. Since different programs have different memory usage patterns, the main issues have always been: how much memory to set aside, and when, for the different uses of allocated memory.

- Icon V6      Originally, Icon expected to control all memory itself. Allocated storage was a single contiguous memory extent. On some systems, it could be expanded using the UNIX `sbrk()` system call.
- Icon V7      In order to port Icon widely, an alternative that did not depend on `sbrk()` was developed in which the allocated storage was split into three fixed size extents (static, string and block).

**Icon V8**      The Icon compiler `iconc` introduced improvements to storage handling. Internally, pointers replace many descriptors in blocks, saving space. The process of registering tensed variables with the garbage collector becomes organized and gains syntactic support via RTL. For the sake of systems like MS-DOS, which had 64K allocation limits, multiple string or block storage regions are allocated if garbage collection fails to provide enough free space to satisfy an allocation request. Storage regions that are full may subsequently have space freed and be reused.

**Icon V9**      By this point, `sbrk()` is abandoned and multiple, fixed regions are standard.

**Unicon**        Each thread uses its own string and block storage regions for allocation. A thread that performs garbage collection must first suspend every other thread before proceeding.

## 11.1 Memory Layout

During the execution of an Icon program, memory is logically divided into several areas based on how the memory is used. The word “region” may generically refer to the different sections in the diagram; in the implementation, it is used more specifically to refer to individually-allocated chunks of memory within the allocated storage area.

The sizes and locations of memory regions are dependent on computer architecture and the operating system used, but typically they have the following form:

This diagram is not drawn to scale; some regions are much larger than others. It is also an abstraction; the regions might or might not be contiguous, and each is allocated separately. The free space is managed by the underlying operating system rather than by the Icon runtime.

**The Run-Time System.** The run-time system contains the executable code for the interpreter, built-in operators and functions, support routines, and so forth. It also contains static storage for some Icon strings and blocks that appear in C functions. For example, runtime/data.r contains statically-allocated blocks for many runtime system entities such as built-in csets. Such blocks never move, but in some cases their contents may change. [In Unicon, most non-constant data that was global in Icon has been moved into a per-program or per-thread structure.](#) The size of the run-time system is machine-dependent.

**The Icode Region.** One of the first things done by the run-time system is to read in the icode file for the program that is to be executed. The data in the icode region, which is produced by the linker, is divided into a number of sections:

<b>code and blocks</b>
<b>record information</b>
<b>global identifier values</b>
<b>global identifier names</b>
<b>static identifier values</b>
<b>strings</b>

The first section contains virtual machine code, blocks for cset and real literals, and procedure blocks, on a per-procedure basis. Thus, the section of the icode region that contains code and blocks consists of segments of the following form for each procedure:

<b>blocks for real literals</b>
<b>blocks for cset literals</b>
<b>procedure blocks</b>
<b>virtual machine instructions</b>

Record information for the entire program is in the second section of the icode region. Next, there is an array of descriptors for the values of the global identifiers in the program, followed by an array that contains qualifiers for the names of the global identifiers. These two arrays are parallel. The *ith* descriptor in the first array contains the value of the *ith* global identifier, and the *ith* descriptor in the second array contains a qualifier for its name.

Following the two arrays related to global identifiers is an array for the values of static identifiers. As mentioned in Sec. 2.1.10, static identifiers have global scope with respect to procedure invocation, but a static identifier is accessible only to the procedure in which it is declared.

Unlike cset and real blocks, which are compiled on a per-procedure basis, all strings in a program are pooled and are in a single section of the icode region that follows the array of static identifiers. A literal string that occurs more than once in a program occurs only once in the string section of the icode region.

Data in the icode region is never moved, although some components of it may change at run time. The size of the icode region depends primarily on the size of the corresponding source program. As a rule of thumb, an icode region is approximately 2-4x as large as the corresponding Icon source-language file.

**Allocated Storage.** The space for data objects that are constructed at run time is provided in allocated storage regions. Historically this portion of memory consisted of three parts: a static region, a string region, and a block region.

The static region was originally just for co-expression blocks. Once expandable regions via `sbrk()` were retired, the management of static region(s) was returned to the C library, using standard functions such as `malloc()` and `free()`.

The remaining allocated storage regions are divided into strings and blocks as shown. The string region contains only characters. The block region, on the other hand, contains pointers. This leads to a number of differences in allocation and garbage-collection techniques in different regions.

The initial sizes of the allocated storage regions vary considerably from computer to computer, depending on the size of the user address space. In Icon, initial sizes of 500,000 bytes or 2,000,000 bytes per region are common. [Unicon allocates a percentage of available memory for each string](#)

and block region. The user may establish different initial sizes prior to program execution by using environment variables STRSIZE and BLKSIZE. As indicated previously, new larger regions are allocated at run time if necessary, but there is no provision for decreasing the size of a region once it has been allocated a given size.

If a string or block region cannot satisfy a storage request after it has been garbage collected, a new region is allocated and the old region placed in a pool of available regions. Subsequently, as part of the processing to allocate new storage, if the current region cannot satisfy the request the pool is searched to see if there is an existing region that can satisfy the request. Only if no region can satisfy the request is a new region allocated (and the old region assigned to the pool).

**In concurrent Unicon programs, each thread allocates from its own string and block regions.**

**Free Space and the Stacks.** It was originally intended that the “free space” depicted in the diagram at the top of this section would be managed by the Icon runtime system, cleverly sharing this memory between the allocated storage (heaps) and system stack as needed. Some programs might use more structures, while others might employ algorithms that were stack-heavy.

In fact, the implementation of Icon was never this simple. The system stack grew downwards on some systems and upwards on others, and there was also an interpreter stack. After the introduction of multiple regions, the notion of “free space” was given up (or assumed to be managed by the C library and/or operating system) and Icon and Unicon more or less came to accept a massively fragmented memory model. New heaps can be allocated as needed, but all stacks (except the system stack, also called the C stack) had better be big enough up front.

System stacks may be limited in size by the operating system, although on some systems the program can request increases and on other systems the size is very large. Besides the possibility of a heavily recursive Icon or Unicon algorithm needing a very large stack, the implementor must also recognize that the garbage collection algorithm is recursive, and given large enough structures, it will trigger stack overflows and machine crashes.

## 11.2 Allocation

Storage allocation in Icon is designed to be fast and simple. Garbage collection is somewhat more complicated as a result. Part of the rationale for this approach is that most Icon programs do a considerable amount of allocation, but many programs never do a garbage collection. Hence, programs that do not garbage collect are not penalized by a strategy that makes garbage collection more efficient at the expense of making allocation less efficient. The other rationale for this approach is that the storage requirements of Icon do not readily lend themselves to more complex allocation strategies.

### 11.2.1 The Static Region

The “static region” is now a logical rather than physical designation, denoting potentially many discontiguous blocks of memory. The term refers generically to data that not managed or moved by the garbage collector. This memory is managed by the C library using its usual semantics.

For example, co-expression blocks are allocated in the static region. Their C stacks contain internal pointers that depend on both the computer and the C compiler and hence are difficult to relocate to another place in memory. The C library routines `malloc()` and `free()` are used to allocate and free co-expression blocks. These routines maintain a list of blocks of free space. The routine `malloc()` finds a block of the requested size, dividing a larger block if necessary, and revises the free list accordingly. The routine `free()` returns the freed space to the free list, coalescing it with adjacent free blocks if possible. See Kernighan and Ritchie 1978 for a discussion of free-list allocation.

### 11.2.2 Blocks

For other kinds of blocks, Icon takes advantage of the fact that its own data can be relocated if necessary and uses a very simple allocation technique. The allocated region for blocks is divided into two parts:

When there is a request for a block of  $n$  bytes, the free pointer, `blkfree`, is incremented by  $n$  and the previous value of the free pointer is returned as the location of the newly allocated block. This process is fast and free of the complexities of the free-list approach.

Note that this technique really amounts to a free list with only one block. The problem of reclaiming fragmented space on the free list is exchanged for the process of reclaiming unused blocks and rearranging the block region so that all the free space is in one contiguous portion of the block region. This is done during garbage collection.

### 11.2.3 Strings

There is even less justification for a free-list approach for allocating strings. A newly created string may be one character long or it may be thousands of characters long. Furthermore, while there is space in blocks that can be used to link together free storage, there is no such space in strings, and a free list would involve additional storage.

Instead, the string region is allocated in the same way that the block region is allocated:

As with the block region, a garbage collection is performed if there is not enough space in the string region to satisfy an allocation request.

## 11.3 Garbage Collection

Allocation is simple, but garbage collection is not. The primary purpose of garbage collection is to reclaim the space occupied by “dead” objects that are not needed for subsequent program execution, so that this space can be reallocated. This means different things in different regions. In the static region, it means freeing dead co-expression blocks. In the string and block regions, it involves moving the space for dead objects from the allocated portion of the region to the free portion. This is considerably more complicated than adding a pointer to a free list. Since all free space must be in a single block in these regions, “live” objects must be moved to fill in the holes left by dead ones. This is done by compacting the allocated portion of these regions, relocating live objects toward the beginning of these regions and squeezing out dead objects. In turn, pointers to live objects have to be adjusted to correspond to their new locations. There are two phases in garbage collection (four in Unicon):

- Suspension of all threads except the thread that wishes to perform a garbage collection.
- Location of live objects and all the pointers to them.
- Compaction of live objects and adjustment of the pointers to them.
- Re-enabling of suspended threads. This may cause further garbage collections if a suspended thread’s regions are “nearly full” — see chapter 30 in Part 3 for details.

“Garbage collection” is somewhat of a misnomer, since the process is oriented toward saving “non-garbage” objects; garbage disappears as a byproduct of this operation.

### 11.3.1 The Basis

The challenging problem for garbage collection is the location of objects that have to be saved, as well as all pointers to them. An object is dead, by definition, if it cannot be accessed by any future source-language computation. Conversely, by definition, an object is live if it can be accessed. Consequently, the important issue is the possibility of computational access. For example, it is always possible to access the value of `&subject`, and this value must be preserved by garbage collection. On the other hand, in

```
a := [1,2,3]
a := list(10)
```

after the execution of the second assignment, the first list assigned to `a` is inaccessible and can be collected.

It is essential to save any object that may be accessed, but there is no way, in general, to know if a specific object *will* be accessed. For example, a computational path may depend on factors that are external to the program, such as the value of data that is read from a file. It does comparatively little harm to save an object that might be accessed but, in fact, never is. Some storage is wasted, but it is likely to be reclaimed during a subsequent collection. It is a serious error, on the other hand, to discard an object that subsequently *is* accessed. In the first place, the former value of such an object usually is overwritten and hence is “garbage” if it is subsequently accessed. Furthermore, accessing such an object may overwrite another accessible object that now occupies the space for the former one. The effects may range from incorrect computational results to addressing violations. The sources of such errors also are hard to locate, since they may not be manifested until considerably later during execution and in a context that is unrelated to the real cause of the problem. Consequently, it is important to be conservative and to err, if at all, on the side of saving objects whose subsequent accessibility is questionable. Note that it is not only necessary to locate all accessible objects, but it is also necessary to locate all pointers to objects that may be relocated.

The location phase starts with a *basis* that consists of descriptors that point to objects that may be accessible and from which other objects may be accessed. For example, `&subject` is in the basis. The precise content of the basis is partly a consequence of properties of the Icon language and partly a consequence of the way the run-time system is implemented. The basis consists of the following descriptors:

- `&main` (co-expression block for the initial call of `main`)
- current co-expression block
- values of global identifiers
- values of static identifiers

- &subject
- saved values of map arguments
- tended descriptors
- file and list values for graphics windows
- (Unicon) per-thread values of keywords and the co-expression block associated with each thread (see Chapter 30 in Part 3)

The tended descriptors provide temporary storage for a run-time support routine in which a garbage collection may occur. See Sec. 12.2.2.

Not all objects that have to be saved are pointed to directly by the basis. The value of a local identifier on the interpreter stack may point to a list-header block that in turn points to a list-element block that contains elements pointing to strings and other blocks. Pointer chains also can be circular.

### 11.3.2 The Location Phase

For historical reasons, the location phase is sometimes called *marking*. This term refers to the common practice of setting an identifying bit in objects that have been located. Not all such processes actually change the objects that are located. The way that this is done in Icon depends on the region in which an object is located.

During the location phase, every descriptor in the basis is examined. A descriptor is of interest only if it is a qualifier or if its v-word contains a pointer (that is, if its d-word contains a p flag). For a pointer `dp` to a descriptor, the following checks are performed:

```

if (Qual(*dp))
    postqual(dp);
else if (Pointer(*dp))
    markblock(dp);

```

where the macro `Pointer(d)` tests the d-word of `d` for a p flag.

**Strings.** The routine `postqual()` first checks that the v-word of the qualifier points to a string in the allocated string region, since strings in other parts of memory are not of interest during garbage collection. If the string is in the allocated string region, a pointer to the qualifier is placed in an array:

```

void postqual(dptr dp)
{
    :
    if (InRange(strbase, StrLoc(*dp), strfree+1)) {
        *qualfree++ = dp;
    }
}

```

The array `quallist` is empty when garbage collection begins. Its size is checked before a pointer is added to it, and more space is obtained if it is needed although the code for doing that is not shown here. See Sec. 11.3.6.

The pointers that accumulate in `quallist` during the marking phase provide the information necessary to determine the portion of the allocated string region that is in use. In addition, these pointers point to all the qualifiers whose *v*-word must be adjusted when the strings they point to are moved during the compaction of string region. See Sec. 11.3.3.

**Blocks.** The location phase for blocks is more complicated than that for strings, since blocks may contain block pointers to other blocks as well as descriptors that either point to strings or point to other blocks. The objects that these pointers and descriptors point to must be processed also.

Unlike strings, in which a separate array is used to keep track of qualifier that have been located, no extra space is needed to keep track of descriptors that point to blocks. Instead, block pointers, descriptors and the titles of the blocks they point to are modified temporarily.

The title of any block located in the allocated block region is changed to point to a *back chain* that contains all the descriptors and block pointers that point to that block. The descriptors are linked through their *v*-words.

The following example illustrates the process. Suppose there is a record declaration

```
record term(value, code, count)
```

and that the following expressions are evaluated:

```

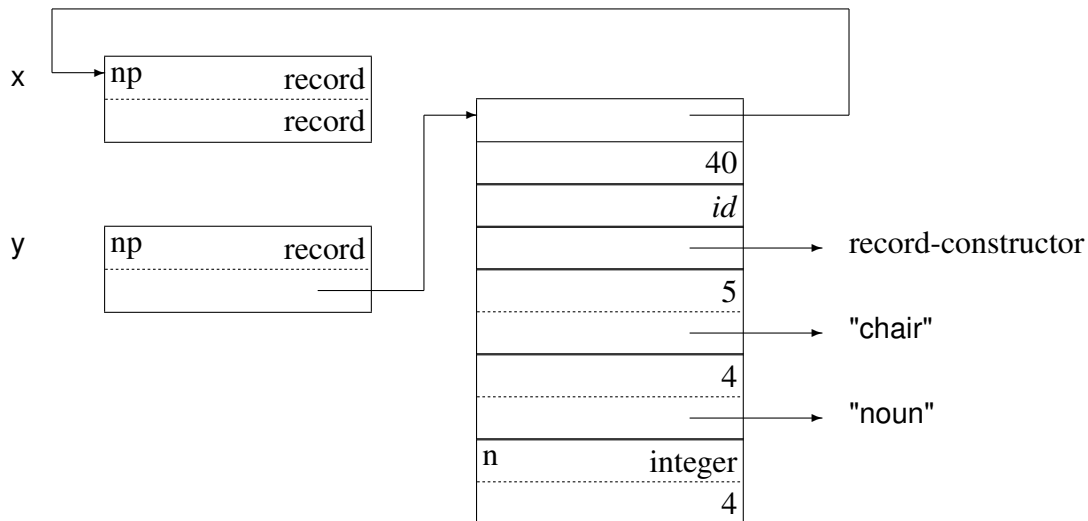

x := term("chair", "noun", 4)
y := x

```

The values of *x*, *y*, and the block they point to are related as follows:

Suppose that the descriptor containing the value of *x* is processed during the location phase before the descriptor containing the value of *y*. This descriptor is identified as pointing to a block in the allocated block region by virtue of the *p* flag in its *d*-word and an address range check on the value of its *v*-word. The back chain is established by setting the title word of the block to point to the descriptor and setting the *v*-word of the descriptor to hold the previous contents of the title word. The result is

The title word of the block now points to the descriptor that previously pointed to the block. This change is reversible, and prior to the completion of the garbage collection process the previous relationship is restored. A crucial but somewhat subtle aspect of the change is that it is now possible to tell that the block has been marked. The numerical magnitude of the value of its title word is greater than that of any type code, since all descriptors in the run-time system are at memory locations whose addresses are larger than the largest type code.

The descriptors in the record block now are processed in the same way as descriptors in the

basis. In order to do this, it is necessary to know where descriptors are located in the block. Since blocks in the allocated block region are organized so that all descriptors follow all non-descriptor data, it is only necessary to know where the first descriptor is and how large the block is. These values are determined using two arrays that have entries for each type code.

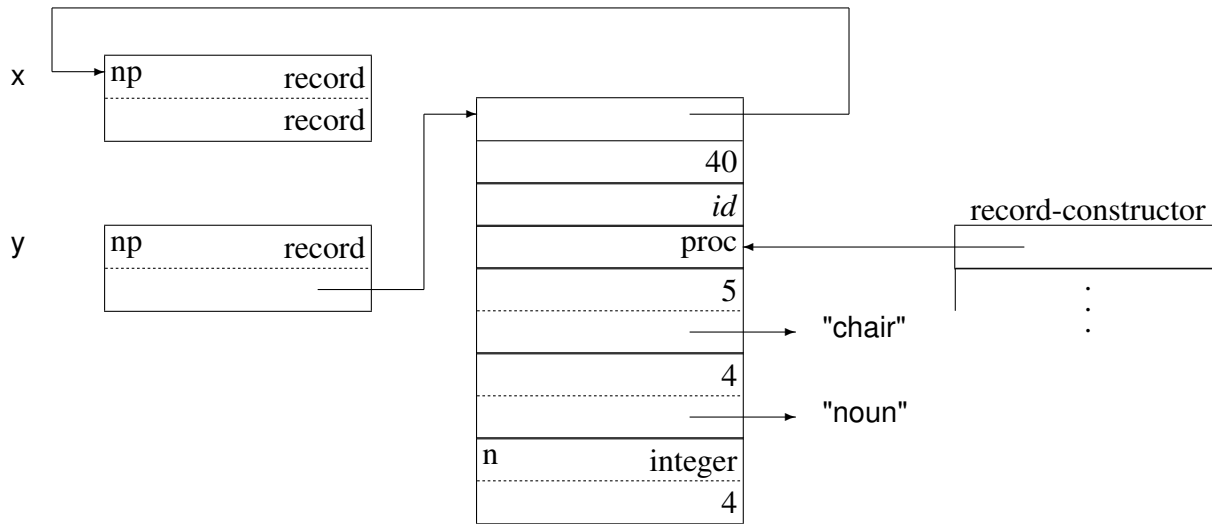

The first array, `bsizes`, provides the information that is needed to determine block sizes. There are three kinds of entries. An entry of -1 indicates a type for which there is no block or for which the blocks are not in the allocated block region. Examples are `T_Null` and `T_Coexpr`. An entry of 0 indicates that the size of the block follows the block title. This is the case for records. Any other entry is the actual size of the block in bytes. For example, the entry in `bsizes` for `T_List` is 24 on a 32-bit computer.

The second array, `firstd`, is used to determine the byte offset of the first descriptor in the block. As with `bsizes`, a value of -1 indicates a type for which there are no associated blocks in the allocated block region. A value of 0 indicates that there are no descriptors in the block. Examples are `T_Cset` and `T_Real`. For `T_Record`, the entry is 8 for 32-bit computers, indicating that the first descriptor is at an offset of 8 bytes (2 words) from the beginning of the block. See Sec. 4.2.

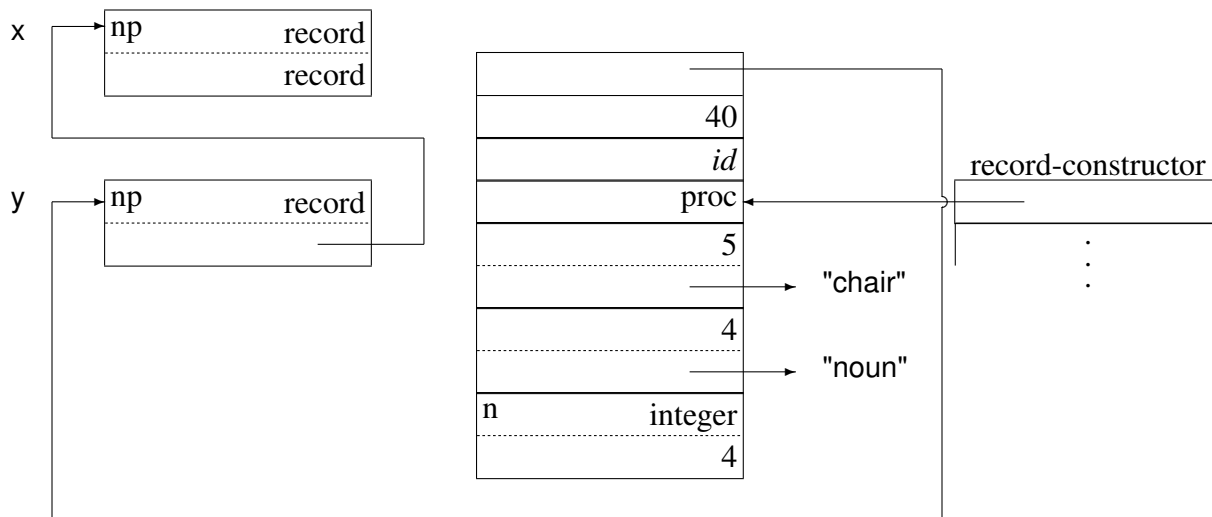

Extra information is required to handle blocks that contain block pointers. It is necessary to know the location of pointers within the block. Two further arrays contain this information. The first array, `firstp`, contains the offset in bytes from the start of the block to the first block pointer. There are three kinds of entry. An entry of -1 indicates a type for which there are no allocated blocks. A value of 0 means that there are no block pointers. Any other value is the offset in bytes of the first block pointer. The second array, `ptrno` contains the number of block pointers in the block. As with `firstp`, an entry of -1 denotes a type for which there are no allocated blocks. 0 means that the rest of the block contains block pointers and a positive value indicates that there are exactly that many block pointers.

The constraint that this design places on the implementation is that all the block pointers must be contiguous within a block and (since the descriptors must be at the end) before any descriptors. Any block that may have a variable number of block pointers must have no descriptors and the pointers must be located at the end of the block.

There is only one block pointer in a record, which points to the record constructor (of type `proc`). The result after processing the record block is that the record constructor block's back chain points to the block pointer in the record block (the record constructor block structure is not shown in detail).

For the previous example, after the block pointers and descriptors in the record block are processed, the location phase continues. When the descriptor that contains the value of *y* is processed, it is added to the back chain by again exchanging the contents of its *v*-word with the contents of the title of the block. As a result, the title of the block points to the descriptor for the value of *y* and its *v*-word points to the descriptor for the value of *x*:

Since the title of the block that *y* points to is marked, the descriptors in it are not processed. This prevents descriptors from being processed twice and also prevents the marking phase from looping in case there are pointer loops among blocks.

If a variable descriptor is encountered when processing descriptors whose *d*-words contain *p* flags, the value the variable points to belongs to one of the following categories:

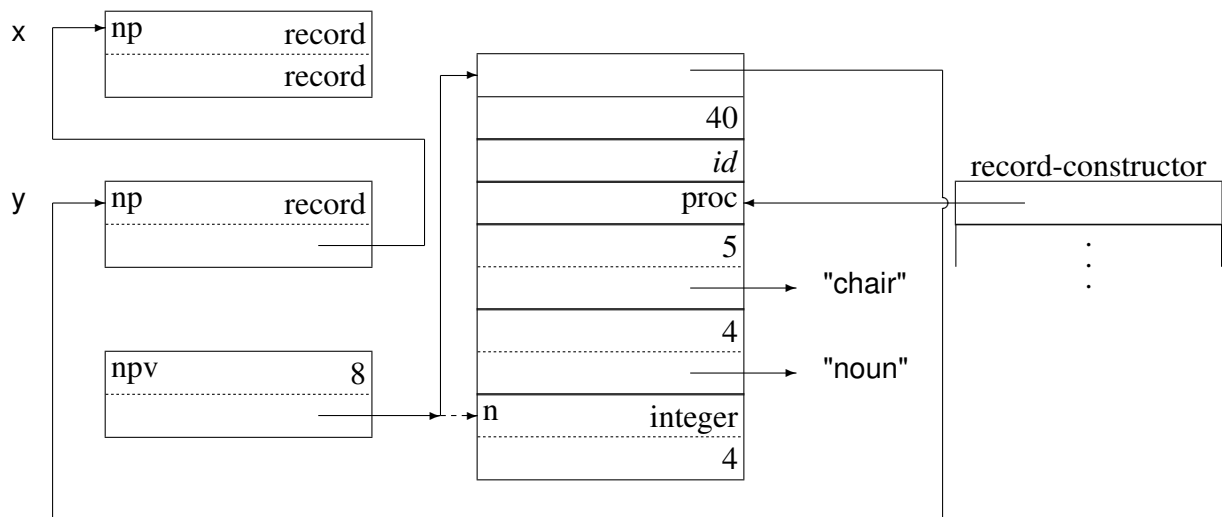

- trapped-variable block
- global or static identifier
- argument or local identifier

A trapped variable, indicated by a *t* flag in its *v*-word, points to a block and is processed like any other descriptor that points to a block. The values of global and static identifiers are in the basis and are processed separately. The values of arguments and local identifiers are on an interpreter stack and are processed when its co-expression block is processed.

Continuing the previous example, suppose that a garbage collection is triggered by evaluation of the expression

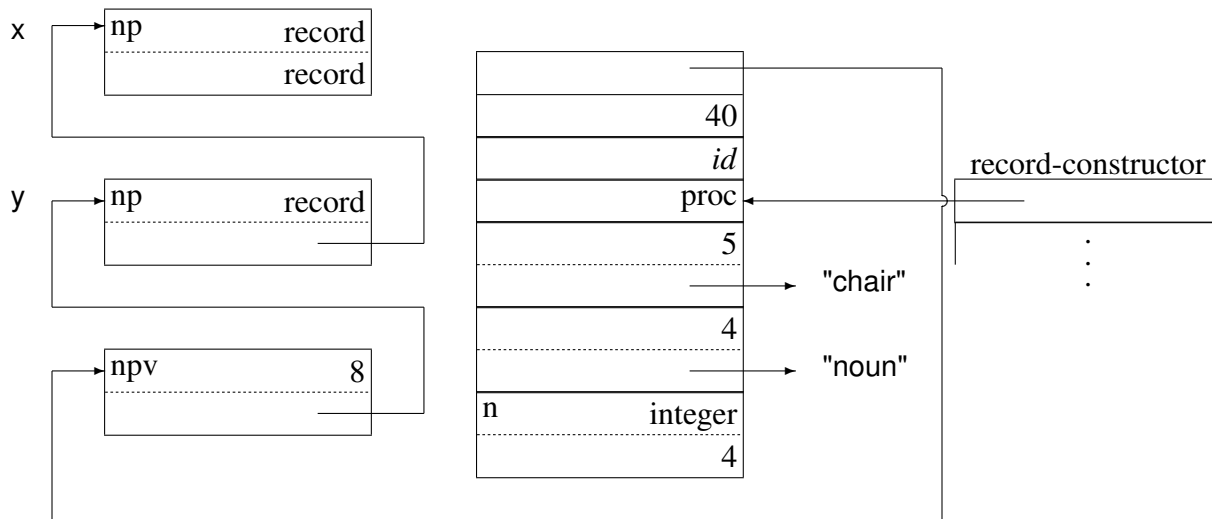

`x.count := read()`

At the beginning of garbage collection, there is a variable descriptor for the field reference that points to the record block in addition to the descriptors for the values of *x* and *y*. If the values of *x* and *y* are processed first as described previously, the situation when the variable descriptor is encountered is

Note that the offset in the *d*-word of the variable descriptor is in words, not bytes.

When the location phase is complete, the title of each block in the allocated block region that must be saved points to a chain of all the descriptors that originally pointed to it. This provides the necessary information to adjust the v-words of these descriptors to account for the relocation of the block during the compaction phase. See Sec. 11.3.3.

If a descriptor that points to a co-expression block is encountered during the location phase, the title of the co-expression block is marked and the descriptors in the co-expression block are processed in a fashion similar to that for blocks in the allocated block region. Since co-expression blocks are never moved, it is not necessary to keep track of descriptors that point to them. To mark the title, it is sufficient to change it to a value that is larger than any type code.

The activator of the co-expression (if any) is processed like any other co-expression block. Similarly, the refresh block that is pointed to from the co-expression block must be processed like any other block. The rest of the descriptors associated with a co-expression are in its interpreter stack.

Here the situation is more complicated than it is with blocks in the allocated block region, since interpreter stacks contain frame markers in addition to descriptors. Despite this, all the descriptors, and only the descriptors, on an interpreter stack must be processed.

Interpreter stacks are processed by the routine `sweep()`, which starts at `sp` for the stack and works toward the stack base. Descriptors are processed until the next frame marker is encountered, at which point, depending on the type of the frame, the marker is skipped and new frame pointers are set up from it.

The routine for marking blocks is

```
static void markblock(dp)
dptr dp;
{
```

```

register dptr dp1;
register char *block, *endblock;
word type, fdesc;
int numptr;
register union block **ptr, **lastptr;

if (Var(*dp)) {
    if (dp->dword & F_Typeocode) {
        switch (Type(*dp)) {
            case T_Kywdint:
            case T_Kywdpos:
            case T_Kywdsbj:
                /*
                 * descriptor points to a keyword, not a block.
                 */
                return;
        }
    }
    else if (Offset(*dp) == 0) {
        /*
         * A simple variable not residing in a block.
         */
        return;
    }
}

/*
 * Get the block to which dp points.
 */
block = (char *)BlkLoc(*dp);

if (InRange(blkbase,block,blkfree)) {
    type = BlkType(block);
    if ((uword)type <= MaxType) {

        /*
         * The type is valid, which indicates that this block
         * has not been marked. Point endblock to the byte
         * past the end of the block.

```

```

    */
    endblock = block + BlkSize(block);
}

/*
 * Add dp to the back chain for the block and point the
 * block (via the type field) to dp.vword.
 */
BlkLoc(*dp) = (union block *)type;
BlkType(block) = (uword)&BlkLoc(*dp);

if ((uword)type <= MaxType) {
    /*
     * The block was not marked; process pointers and
     * descriptors within the block.
     */
    if ((fdesc = firstp[type]) > 0) {
        /*
         * The block contains pointers; mark each pointer.
         */
        ptr = (union block **)(block + fdesc);
        numptr = ptrno[type];
        if (numptr > 0)
            lastptr = ptr + numptr;
        else
            lastptr = (union block **)endblock;
        for (; ptr < lastptr; ptr++)
            if (*ptr != NULL)
                markptr(ptr);
    }
    if ((fdesc = firstd[type]) > 0)
        /*
         * The block contains descriptors; mark each one.
         */
        for (dp1 = (dptr)(block + fdesc);
            (char *)dp1 < endblock; dp1++) {
            if (Qual(*dp1))
                postqual(dp1);
            else if (Pointer(*dp1))
                markblock(dp1);
        }
    }

```

```

        }
    }
}

else if ((unsigned int)BlkType(block) == T_Coexpr) {
    struct b_coexpr *cp;
    struct astkblk *abp;
    int i;
    struct descrip adesc;

    /*
     * dp points to a co-expression block that has not been
     * marked. Point the block to dp. Sweep the interpreter
     * stack in the block. Then mark the block for the
     * activating co-expression and the refresh block.
     */
    BlkType(block) = (uword)dp;
    sweep((struct b_coexpr *)block);

    /*
     * Mark the activators of this co-expression. The
     * activators are stored as a list of addresses, but
     * markblock requires the address of a descriptor. To
     * accommodate markblock, the dummy descriptor adesc is
     * filled in with each activator address in turn and then
     * marked. Since co-expressions and the descriptors that
     * reference them don't participate in the back-chaining
     * scheme, it's ok to reuse the descriptor in this manner.
     */
    cp = (struct b_coexpr *)block;
    adesc.dword = D_Coexpr;
    for (abp = cp->es_actstk; abp!=NULL; abp = abp->astk_nxt) {
        for (i = 1; i <= abp->nactivators; i++) {
            BlkLoc(adesc) =
                (union block *)abp->arec[i-1].activator;
            markblock(&adesc);
        }
    }
    if(BlkLoc(cp->freshblk) != NULL)

```

```

        markblock(&((struct b_coexpr *)block)->freshblk);
    }
    else {
        /* ... code for blocks found in other regions */
    }
}

```

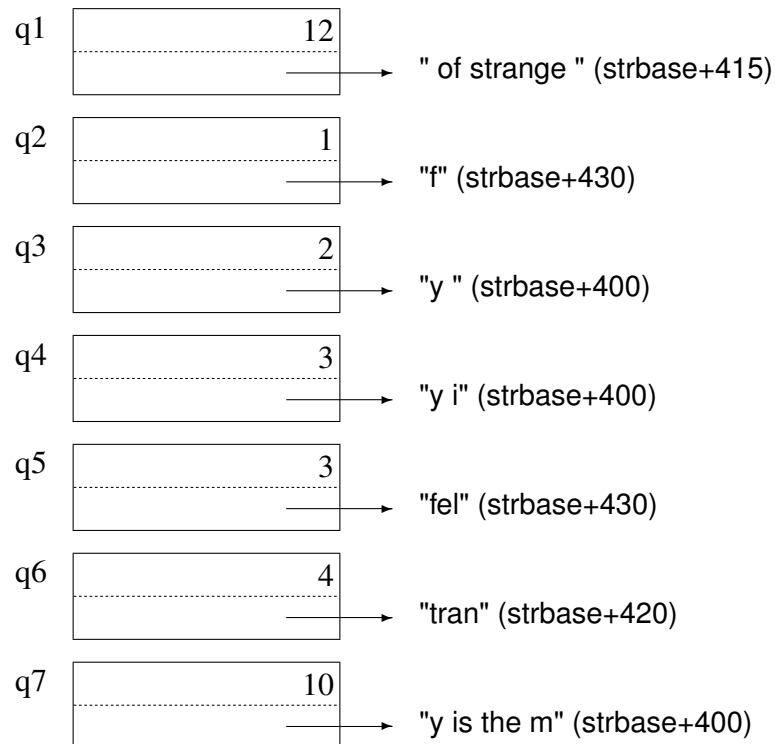

The macro `BlkType(cp)` produces the type code of the block pointed to by `cp`. The macro `BlkSize(cp)` uses the array `bsizes` to determine the size of the block pointed to by `cp`.

### 11.3.3 Pointer Adjustment and Compaction

**Strings.** When the location phase is complete, `quallist` contains a list pointers to all the qualifiers whose v-words point to the allocated string region. For example, suppose that the allocated string region at the beginning of a garbage collection is

... Necessity is the mother of strange bedfellows ...  
 ↑                    ↑    ↑  
 strbase            +400    strfree

Suppose also that the following qualifiers reference the allocated string region:

The pointers to the allocated string region are

Note that the qualifiers point to overlapping strings.

After the location phase, `quallist` might contain the following pointers:

The order of the pointers in `quallist` depends on the order in which the qualifiers are processed: there is no necessary relationship between the order of the pointers in `quallist` and the order of the pointers to the allocated string region.

At the beginning of the pointer-adjustment phase of garbage collection, the array `quallist` is sorted in non-decreasing order by the v-words in qualifiers that are pointed to from `quallist`. This allows the pointers to the allocated string region to be processed in non-decreasing order so that the portions of the allocated string region that must be saved and compacted can be determined.

Continuing the previous example, `quallist` becomes

The v-words of the qualifiers in the order of the pointers in `quallist` now are

```

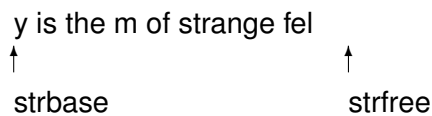

strbase+400
strbase+400
strbase+400
strbase+415
strbase+420
strbase+430
strbase+430

```

Since qualifiers may reference overlapping strings, care must be taken to identify contiguous “clumps” of characters that may be shared by qualifiers. The pointers in `quallist` are processed in order. Three pointers in the string region are maintained: `dest`, the next free destination for a clump of characters to be saved; `source`, the start of the next clump; and `cend`, the end character in the current clump.

When a qualifier that is pointed to from quallist is processed, the first question is whether its v-word addresses a character that is beyond the end of the current clump (since v-words are processed in numerical order, the address is either in the current clump or beyond the end of it). If it is in the current clump, cend is updated, provided the last character of the current qualifier is beyond cend. If it is not in the current clump, the clump is moved from source to dest. In either case, the v-word of the current qualifier is adjusted (dest - source is added to it).

In the previous example, the allocated string region after collection is

and the seven qualifiers that point to it are

```

static void scolect(extra)
word extra;
{
    register char *source, *dest;
    register dptr *qptr;
    char *cend;
    CURTSTATE();

    if (qualfree <= quallist) {
        /*
         * There are no accessible strings. Thus, there are none to
         * collect and the whole string space is free.
         */
        strfree = strbase;
        return;
    }
    /*
     * Sort the pointers on quallist in ascending order of string
     * locations.
     */
    qsort((char *)quallist, (int)(DiffPtrs((char *)qualfree,(char *)quallist)) /
        sizeof(dptr *), sizeof(dptr), (QSortFncCast)qlcmp);
    /*
     * The string qualifiers are now ordered by starting location.
     */
    dest = strbase;
    source = cend = StrLoc(**quallist);

    /*
     * Loop through qualifiers for accessible strings.
     */
    for (qptr = quallist; qptr < qualfree; qptr++) {
        if (StrLoc(**qptr) > cend) {

            /*
             * qptr points to a qualifier for a string in the next clump.
             * The last clump is moved, and source and cend are set for
             * the next clump.
             */

```

```

    while (source < cend)
        *dest++ = *source++;
    source = cend = StrLoc(**qptr);
}
if ((StrLoc(**qptr) + StrLen(**qptr)) > cend)
/*
    * qptr is a qualifier for a string in this clump; extend
    * the clump.
    */
    cend = StrLoc(**qptr) + StrLen(**qptr);
/*
    * Relocate the string qualifier.
    */
    StrLoc(**qptr) = StrLoc(**qptr) + DiffPtrs(dest,source) + (uword)extra;
}

/*
    * Move the last clump.
    */
while (source < cend)
    *dest++ = *source++;
strfree = dest;
}

```

The argument *extra* provides an offset in case the string region is moved. See Sec. 11.3.5.

Sorting is done by the C library routine *qsort*, whose fourth argument is a routine that performs the comparison

```

static int qlcmp(dptr *q1, dptr *q2)
{
    return (int)(DiffPtrs(StrLoc(**q1),Strloc(**q2)));
}

```

**Blocks.** After the location phase, some blocks in the allocated block region are marked and others are not. In the following typical situation, the horizontal lines delimit blocks, gray areas indicate marked blocks, and clear areas indicate unmarked blocks:

In the allocated block region, pointer adjustment and compaction are done in two linear passes over the region between `blkbase` and `blkfree`. In the first pass, two pointers are used, `dest` and `source`. `dest` points to where the next block will be after blocks are moved in the next pass, while `source` points to the next block to be processed. Both `dest` and `source` start at `blkbase`, pointing to the first allocated block.

During this pass, the title of each block pointed to by `source` is examined. If it is not marked (that is, if it is not larger than the maximum type code), `dest` is left unchanged and `source` is incremented by the size of the block to get to the title of the next block. Thus, unmarked blocks are skipped. The array `bsizes` is used, as before, to determine block sizes.

If the title of the block pointed to by `source` is marked, its back chain of descriptors is processed, changing their v-words to point to where `dest` points. Version 6 of Icon (where some variable descriptors pointed to *within* blocks) needed to treat such descriptors specially to account for the extra offset. A previous edition of this book said

“A variable descriptor that points to a descriptor in a structure points *within* a block, not to the title of a block. This is the only case in which the offset, which is contained in the least-significant portion of the d-word of a non-trapped-variable descriptor, is nonzero. Consequently, this offset is used to distinguish such variables.”

⋮

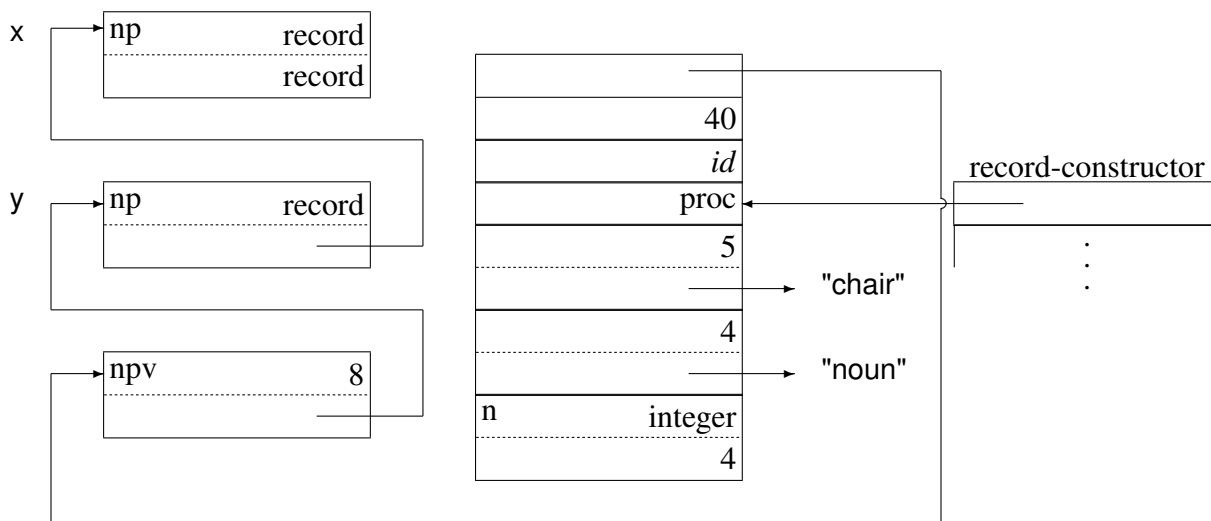

“In the case of a variable descriptor that is not a trapped-variable descriptor, the offset in its d-word is added to its v-word, so that it points to the appropriate relative position with respect to `dest`.”

Unfortunately in version 8 of Icon, which substituted block-pointers for the descriptors in blocks that pointed to other blocks (and hence introduced block-pointers into the back chain), it is no longer possible to identify offset descriptors because the value of the word immediately before the

pointer in the chain can no longer be guaranteed to be the d-word of a descriptor. As a consequence, *all* descriptors now point to the start of the block, so the previous special case is no longer necessary. The previous treatment of offset descriptors was an optimization for speed of access during normal execution. With the introduction of block-pointers, which make all blocks smaller, we have effectively traded a reduction in space for all programs for a slightly increased execution time in some cases.

The last descriptor in the back chain is identified by the fact that its v-word contains a type code (a value smaller than any possible pointer to the allocated block region). This type code is restored to the title of the block before the v-word is changed to point to the destination. An m flag is set in the title to distinguish it as a marked block, since the former marking method no longer applies, but the compaction phase needs to determine which blocks are to be moved.

After the back chain has been processed, all descriptors that point to the block now point to where the block *will be* when it is moved during the compaction phase. The block itself is not moved at this time. This is illustrated by the example given previously, in which three descriptors point to a record block. After marking, the situation is

After processing the back chain, the situation is

Note that the v-words of the descriptors point to where the block *will be* after it is moved. When the record constructor block is encountered and processed (assuming the value of `dest` at that time is `dest_rc`), the situation becomes

The routine for adjusting pointers to the allocated block region is

```
static void adjust(char *source, char *dest)
{
    register union block **nxtptr, **tptr;

    /*
     * Loop through to the end of allocated block region, moving
     * source to each block in turn and using the size of a block
```

```

    * to find the next block.
    */
while (source < blkfree) {
    if ((uword)(nxtptr = (union block **)BlkType(source)) >
        MaxType) {

        /*
         * The type field of source is a back pointer. Traverse
         * the chain of back pointers, changing each block
         * location from source to dest.
         */
        while ((uword)nxtptr > MaxType) {
            tptr = nxtptr;
            nxtptr = (union block **) *nxtptr;
            *tptr = (union block *)dest;
        }
        BlkType(source) = (uword)nxtptr | F_Mark;
        dest += BlkSize(source);
    }
    source += BlkSize(source);
}

```

When the pointer-adjustment phase is complete, the blocks can be moved. At this time, all the block titles contain type codes, and those that are to be saved are marked by m flags. During the compaction phase, these pointers are used again to reference the destination and source of blocks to be moved.

If an unmarked block is encountered, source is incremented by the block skipping over the block. If a marked block is encountered, the m flag in its is removed and the block is copied to dest. Then dest and source are incremented by the size of the block.

When blkfree is reached, it is set to dest. At this point the allocated block region has been compacted. All saved blocks are before blkfree, and all free space is after it. The pointers that were adjusted now point to their blocks, and the relative situation is the same as it was before garbage collection.

The routine for compacting the allocated block region is

```

static void compact(source)
char *source;
{

```

```

register char *dest;
register word size;

/*
 * Start dest at source.
 */
dest = source;

/*
 * Loop through to end of allocated block space, moving source
 * to each block in turn, using the size of a block to find
 * the next block. If a block has been marked, it is copied
 * to the location pointed to by dest and dest is pointed
 * past the end of the block, which is the location to place
 * the next saved block. Marks are removed from the saved
 * blocks.
 */
while (source < blkfree) {
    size = BlkSize(source);
    if (BlkType(source) & F_Mark) {
        BlkType(source) &= ~F_Mark;
        if (source != dest)
            mvc((uword)size, source, dest);
        dest += size;
    }
    source += size;
}

/*
 * dest is the location of the next free block. Now that
 * compaction is complete, point blkfree to that location.
 */
blkfree = dest;
}

```

The routine `mvc(n, source, dest)` moves `n` bytes from `source` to `dest`.

### 11.3.4 Collecting Co-Expression Blocks

After the location phase of garbage collection is complete, all the live co-expression blocks are marked, but the dead co-expression blocks are not. It is a simple matter to process the list of co-expression blocks, which are linked by pointers, calling `free` to deallocate dead ones and at the same time removing them from the list. For live co-expressions, the type code in the title is restored. The routine `cofree` that frees co-expression blocks is

```
static void cofree()
{
    register struct b_coexpr **ep, *xep;

    /*
     * Reset the type for &main.
     */
    BlkLoc(k_main)->coexpr.title = T_Coexpr;
    /*
     * The co-expression blocks are linked together through their
     * nextstk fields, with stklist pointing to the head of the
     * list. The list is traversed and each stack that was not
     * marked is freed.
     */
    ep = &stklist;
    while (*ep != NULL) {
        if (BlkType(*ep) == T_Coexpr) {
            xep = *ep;
            *ep = (*ep)->nextstk;
            /*
             * Free the astkblks. There should always be one and it
             * seems that it's not possible to have more than one,
             * but nonetheless, the code provides for more than one
             */
            for (abp = xep->es_actstk; abp; ) {
                xabp = abp;
                abp = abp->astk_nxt;
                free((pointer)xabp);
            }
            coclean(xep->cstate);
            free((char *)xep);
        }
    }
}
```

```

    }
    else {
        BlkType(*ep) = T_Coexpr;
        ep = &(*ep)->nextstk;
    }
}

```

### 11.3.5 Multiple Regions

Garbage collection may not produce enough free space in a region to satisfy the request that caused the garbage collection. In this case, the region for which the request was made is replaced with a new larger region. In addition, the allocated string and block regions are replaced if the amount of free space in them after garbage collection otherwise would be less than a minimum value, which is called “breathing room.” This attempts to avoid “thrashing” that might result from a garbage collection that leaves a small amount of free space, only to result in a subsequent garbage collection almost immediately.

The set of string and block regions for a program are managed as a linked list. Older, “tenured” regions are revisited, and garbage collected, prior to allocating new, larger regions. If an older region frees enough space, it is made the active region instead of allocating a new one.

Unicon takes advantage of multiple regions to implement the storage allocations made by threads efficiently. Each thread has its own string and block region from which it makes allocations. This design avoids delays caused by mutual exclusion, which would be necessary if the threads shared a common string or block region.

Note that the use of a dedicated per-thread region does not mean that a thread may perform a garbage collection whilst other threads are running. Although it is likely that most of the data in a thread’s dedicated region has been allocated by the thread itself, because the regions can be swapped between threads (by a region becoming full, then being garbage collected and assigned to another thread) there is no guarantee that *all* of the allocations in a thread’s dedicated region have been made by that thread. Furthermore, threads may pass references to each other’s data structures which makes it necessary to suspend all threads to sweep across all regions and update any shared references.

A thread that requires a garbage collection must first suspend all the other threads before proceeding, which it does by signalling to the runtime system that a collection is required: Each thread checks whether a garbage collection request has been made after every instruction. If so it suspends itself.

Chapter 30 in Part 3 has more details of storage layout for multi-threaded programs and how garbage collection is coordinated when several threads are active.

### 11.3.6 Storage Requirements during Garbage Collection

Garbage collection itself takes some work space. Space for pointers to qualifiers is provided in `quallist`, while C stack space is needed for calls to routine that perform the various aspects of garbage collection, which are heavily recursive.

The space for `quallist` is obtained from the free space at the end of the allocated block region. The amount of space needed is proportional to the number of qualifiers whose v-words point to strings in the allocated string region and usually is comparatively small. Space for `quallist` is obtained in small increments

This is done in `postqual()`, for which the complete routine is

```
static void postqual(dptr dp)
{
    char *newqual;

    if (InRange(strbase, StrLoc(*dp), strfree + 1)) {
        /*
         * The string is in the string space. Add it to the string
         * qualifier list, but before adding it, expand the string
         * qualifier list if necessary.
         */
        if (qualfree >= equallist) {
            /* reallocate a qualifier list that's twice as large */
            newqual = realloc(quallist, 2 * qualsize);
            if (newqual) {
                quallist = (dptr *)newqual;
                qualfree = (dptr *)(newqual + qualsize);
                qualsize *= 2;
                equallist = (dptr *)(newqual + qualsize);
            }
            else {
                qualfail = 1;
                return;
            }
        }
        *qualfree++ = dp;
    }
}
```

The amount of stack space required during garbage collection depends primarily on the depth

of recursion in calls to `markblock()` and `markptr()`. Recursion in these functions corresponds to linked lists of pointers in allocated storage. It occurs where a descriptor in the static region or the allocated block region points to an as-yet unmarked block. C stack overflow may occur during garbage collection. This problem is particularly serious on computers with small address spaces for programs that use a large amount of allocated data. The use of stack space during marking is minimized by testing descriptor v-words before calling `markblock()`, by using static storage for variables in `markblock()` that are not needed in recursive calls, and by incorporating the code for processing co-expression blocks in `markblock()`, rather than calling a separate routine.

## 11.4 Predictive Need

In most systems that manage allocated storage dynamically, garbage collections are triggered by allocation requests that cannot be satisfied by the amount of free storage that remains. In these systems, garbage collections occur during calls to allocation routines.

Whenever a garbage collection occurs, all potentially accessible data must be reachable from the basis, and any descriptors that are reachable from the basis must contain valid data. These requirements pose serious difficulties, since, in the normal course of computation, pointers to accessible objects may only exist in registers or on the C stack as C local variables that the garbage collector has no way of locating. Furthermore, descriptors that are being constructed may temporarily hold invalid data. While it is helpful to know that garbage collection can occur only during calls to allocation routines, allocation often is done in the midst of other computations. Assuring that all accessible data is reachable and that all reachable data is valid can be difficult and prone to error.

For these reasons, Icon uses a slightly different strategy, called “predictive need,” for triggering garbage collections. Instead of garbage collection occurring as a byproduct of an allocation request, the amount of space needed is requested in advance. There is a routine, `reserve(Region,n)`, for reserving space in advance. This routine checks the specified region to assure the amount of free space needed is actually available. If it is not, it calls the garbage collector. The code for `reserve()` is conceptually

```
char *reserve(int r, uword n)
{
    if (DiffPtrs(regions[r]->end,regions[r]->free < n))
        collect(r,n);
    return regions[r]->free;
}
```

In practice, things are more complicated, as the current region may be changed or a new region may be allocated in order to satisfy the request.

The string allocator mainly ensures space is available and then updates the free pointer:

```

char *alcstr(char *s, word slen)
{
    tended struct descrip ts;
    register char *d;
    char *ofree;

    /*
     * Make sure there is enough room in the string space.
     */
    if (DiffPtrs(strend, strfree) < slen) {
        StrLen(ts) = slen;
        StrLoc(ts) = s;
        if (!reserve(Strings, slen))
            return NULL;
        s = StrLoc(ts);
    }

    strttotal += slen;
    /*
     * Copy the string into the string space, saving a pointer to
     * its beginning. Note that s may be null, in which case the
     * space is still to be allocated but nothing is to be copied
     * into it.
     */
    ofree = d = strfree;
    if (s) {
        while (slen-- > 0)
            *d++ = *s++;
    }
    else
        d += slen;
    strfree = d;
    return ofree;
}

```

If a garbage collection occurs, a parameter is passed to be sure that enough space is collected to satisfy any remaining allocation requests.

Since a predictive need request assures an adequate amount of space, no garbage collection can occur during the subsequent allocation request. The advantage of having a garbage collection occur

during a predictive need request rather than during an allocation request is that a safe time can be chosen for a possible garbage collection. The amount of space needed (or at least an upper bound on it) usually is known before the storage is actually needed, and when all valid data can be located from the basis.

A few lines from the implementation of the `image()` function, showing how string images are constructed, illustrates predictive need. The image will consist of a pair of double quotes, enclosing a representation of the string contents with special characters escaped. If `alcstr()` is called separately for the various components, they might be allocated non-contiguously. Reserving the maximum space needed ahead of time guarantees subsequent calls to `alcstr()` will be contiguous. The maximum needed for image would be `StrLen(source)*4+2`, done using a shift operator:

```
s = StrLoc(source);
len = StrLen(source);
Protect (reserve(Strings,(len << 2) + 2), return Error);
Protect(t = alcstr("\\"", (word)(1)), return Error);
StrLoc(*dp2) = t;
StrLen(*dp2) = 1;
while (len-- > 0)
    StrLen(*dp2) += doimage(*s++, "\");
Protect(alcstr("\\"", (word)(1)), return Error);
++StrLen(*dp2);
```

A disadvantage of predictive need is that the maximum amount of storage needed must be determined and care must be taken to make predictive need requests prior to allocation. These problems do not occur in storage-management systems where garbage collection is implicit in allocation.

**RETROSPECTIVE:** Storage management is one of the major concerns in the implementation of a run-time system in which space is allocated dynamically and automatically. Although many programs never garbage collect at all, for those that do, the cost of garbage collection may be significant.

The requirements of storage management have a significant influence on the way that data is represented in Icon, particularly in blocks. Aspects of data representation that may appear arbitrary in the absence of considerations related to storage management have definite uses during garbage collection.

The garbage collector can only identify those pointers of which it is informed. Globals are informed by placing them in the basis set. Locals are informed by declaring them to be tended. Descriptors and block pointers within blocks are specified in tables, indexed by the block's type code, that describe the number and positional offset of all pointers within the block.

While it is possible to devise more economical methods of representing such data at the expense

of complexity and loss of generality, any method of representing data for which space is allocated automatically has some overhead.

Garbage collection is most expensive when there are many live objects that must be saved. For programs in which allocated storage is used transiently and in which there are few live objects, garbage collection is fast.

## EXERCISES

**11.1** Since the first word of a block contains its type code, why is there also a type code in a descriptor that points to it?

**11.2** *Question removed: it no longer applies.*

**11.3** Give an example of an Icon expression that changes data in the icode region.

**11.4** Why not combine global and static identifiers in a single array of descriptors in the icode region?

**11.5** Why are the names of global identifiers needed?

**11.6** Why is there no array for the names of static identifiers?

**11.7** How long can a string be?

**11.8** How many elements can a single list-element block hold?

**11.9** List all the regions of memory in which the following Icon data objects can occur:

- strings
- descriptors
- co-expression blocks
- other blocks

**11.10** List all the source-language operations in Icon that may cause the allocation of storage.

**11.11** Give an example of an expression for which it cannot be determined from the expression itself whether or not it allocates storage.

**11.12** List the block types for which block size may vary from one block to another.

**11.13** List all the types of blocks that may occur in the allocated block region.

**11.14** List all the types of blocks that may occur outside of the allocated block region.

**11.15** Give an example of an Icon program in which the only access path to a live object during garbage collection is a variable that points to an element in a structure.

**11.16** Give an example of an Icon program that constructs a circular pointer chain.

**11.17** Explain how it can be assured that all blocks in the allocated block region are at addresses that are larger than the maximum type code.

**11.18** Aside from the possibility of looping in the location phase of garbage collection, what are the possible consequences of processing the descriptors in a block more than once?

**11.19** What would happen if there were more than one pointer on quallist to the *same* qualifier?

**11.20** Because of the way that the Icon run-time system is written, blocks that are not in the allocated block region do not contain pointers to allocated objects. Consequently, the descriptors in such blocks do not have to be processed during garbage collection.

- What does this imply about access to such blocks?
- What changes would have to be made to the garbage collector if such blocks could contain pointers to allocated objects?

**11.21** *Question removed: it no longer applies.*

**11.22** In the allocated string region, pointer adjustment and compaction are done in one pass, while two passes are used in the allocated block region. Why are pointer adjustment and compaction not done in a single pass over the allocated block region?

**11.23** What would be the effect of failing to remove the m flag from a block title during the compaction of the allocated block region?

**11.24** *Question removed: it no longer applies.*

**11.25** Write a program that requires an arbitrarily large amount of space for quallist.

**11.26** Write a program that causes an arbitrary amount of recursion in markblock during garbage collection.

**11.27** Write a program that produces an arbitrarily large amount of data that must be saved by garbage collection, and observe the results.

**11.28** Devise a more sophisticated method of preventing thrashing in allocation and garbage collection than the fixed breathing-room method.

**11.29** There is no mechanism to reduce the size of an allocated region that may be expanded during one garbage collection, but which has an excessive amount of free space after another garbage collection. Describe how to implement such a mechanism.

**11.30** Suppose that a garbage collection could occur during a call of any C routine from any other C routine. How would this complicate the way C routines are written?

**11.31** What might happen if

- The amount of storage specified in a predictive need request were larger than the amount subsequently allocated?
- The amount of storage specified in a predictive need request were smaller than the amount subsequently allocated?

**11.32** When a list-element block is unlinked as the result of a pop, get, or pull, can the space it occupies always be reclaimed by a garbage collection? What are the general considerations in answering questions such as these?

**11.33** A variable that refers to a descriptor in a block points directly to the descriptor, with an offset in its d-word to the head of the block in which the descriptor resides. Could it be the other way

around, with a variable pointing to the head of the block and an offset to the descriptor? If so, what are the advantages and disadvantages of the two methods?

**11.34** Why does sweep process an interpreter stack from its sp to its base, rather than the other way around?

**11.35** As mentioned in Sec. 11.3, all regions are collected, regardless of the region in which space is needed. Discuss the pros and cons of this approach.

**11.36** Evaluate the cost of using two-word descriptors for all pointers to blocks, even when these pointers do not correspond to source-language values (as, for example, in the links among list-element blocks).

**11.37** The need to garbage-collect blocks that are allocated during program execution significantly affects the structure and organization of such blocks. Suppose that garbage collection were never needed. How could the structure and organizations of blocks be revised to save space?

**11.38** Discuss the pros and cons of having different regions for allocating blocks of different types.

**11.39** Some expressions, such as

```
while write(read())
```

result in a substantial amount of “storage throughput,” even though no space really needs to be allocated. Explain why this effect cannot be avoided in general and discuss its impact on program performance.

**11.40** Physical memory is becoming less and less expensive, and more computer architectures and operating systems are providing larger user address spaces. Discuss how very large user address spaces might affect allocation and garbage-collection strategies.

# Chapter 12

## Run-Time Support Operations

PERSPECTIVE: Several features of Icon's run-time system cannot be compartmentalized as neatly as storage management but present significant implementation problems nonetheless. These features include type checking and conversion dereferencing and assignment, input and output, and diagnostic facilities.

### 12.1 Type Checking and Conversion

Type checking is relatively straightforward in Icon. If only one type is of interest a test of the d-word is sufficient, as in

```
if (Type(Arg1) != T_List)
    runerr(108, &Arg1);
```

It is necessary to test the entire d-word, since a qualifier may have a length that is the same as a type code. The d-word test takes care of this, because all descriptors that are not qualifiers have n flags.

If different actions are needed for different types, a separate test is required for qualifiers, since there is no type code for strings. The RTL runtime language's `type_case` statement looks like a switch, but is really performing a selection according to type generally of the form:

```
if (is:string(Arg1)) /* string */
    :
else switch (Type(Arg1)) {
    case T_List: /* list */
        :
    :
```

The real problems lie in type conversion, not type checking. At the source-language level, type conversion can occur explicitly, as a result of type-conversion functions, such as `string(x)`, or it may be implicit. Implicit type conversion occurs frequently in many kinds of computations. For example, numeric data may be read from files in the form of strings, converted to numbers in arithmetic computations, and then converted to strings that are written out. Many operations support this implicit type conversion, and they rely on type-conversion routines.

There are four types among which mutual conversion is supported: strings, csets, integers, and real numbers. The details of type conversion are part of the Icon language definition (Griswold and Griswold 1983). For example, when a cset is converted to a string, the characters of the resulting string are in lexical order. Some conversions are conditional and may succeed or fail, depending on the value being converted. For example, a real number can be converted to an integer only if its value is in the range of a C long. The conversions are illustrated in the following diagram, where dashed lines indicate conversions that are conditional:

Thus, of the twelve conversions, five are conditional.

Some kinds of conversions are “natural” and occur frequently in typical programs. Examples are string-to-integer conversion and integer-to-string conversion. Other conversions, such as cset-to-integer, are unlikely to occur in the normal course of computation. To reduce the number of conversion routines required, these unlikely conversions are done in two steps. For example, the conversion of a cset to an integer is done by first converting the cset to a string and then converting the string to an integer. The direct conversions are

Conversions are done by calling routines that convert values to expected types. These routines are

<code>cnv_cset</code>	convert to cset
<code>cnv_int</code>	convert to integer
<code>cnv_real</code>	convert to real
<code>cnv_str</code>	convert to string

Since these routines may be called with any type of value, all of them are conditional. For example, it is not possible to convert a list to a string. These routines return the value `CvtFail` to indicate the failure of a conversion. If conversion is successful, they return a value indicating the type of conversion.

Numerical computation introduces complications in addition to the types integer and real, since there is the concept of a numeric “type” that includes both integers and real numbers. This is represented explicitly by the Icon type-conversion function `numeric(x)`, which converts `x` to either integer or real, depending on the value of `x`. Its implementation illustrates RTL’s extensions to the C language for type conversions. Rtt can generate special-case functions for each call to `numeric(x)`, based on what it knows about the type information at that call site, and skip the checks and conversions where they are not necessary.

```
function{0,1} numeric(n)
  if cnv:(exact)integer(n) then {
    abstract { return integer }
    inline { return n; }
  }
  else if cnv:real(n) then {
```

```

        abstract { return real }
        inline { return n; }
    }
else {
    abstract { return empty_type }
    inline { fail; }
}
end

```

Numeric conversion also occurs implicitly in polymorphic operations such as

$n+m$

which performs integer or real arithmetic, depending on the types of  $n$  and  $m$ . The RTL language was given an `arith_case` construct specifically to handle this issue. The general form of the arithmetic operators looks like:

```

operator{1} icon_op func_name(x, y)
    declare {
        tended struct descrip lx, ly;
C_integer irslt;
    }
    arith_case (x, y) of {
        C_integer: {
            abstract { return integer }
            inline {
                extern int over_flow;
                c_int_op(x,y);
            }
        }
        integer: { /* large integers only */
            abstract { return integer }
            inline {
                big_## c_int_op(x,y);
            }
        }
        C_double: {
            abstract { return real }
            inline {
                c_real_op(x, y);
            }
        }
    }

```

```

    }
  }
end

```

Internally, a macro `GetReal()` is used to handle the real type, since some computers have restrictions on the alignment of doubles. Thus, `GetReal()` has different definitions depending on the target computer. The actual conversion of a string to a numeric value is done by `ston()`. Note that the conversion of a cset to a numeric value occurs by way of conversion to a string.

When types are not known at compile-time, RTL constructs such as `cnv:str(d)` are translated down to conversion routines in `cnv.r`. String conversion requires a buffer to construct the string. In a common special-case, this buffer is provided by the routine that is requesting string conversion for temporary use, avoiding the heap memory allocator. This is used, for example when a value is converted to a string in order to convert it to a number. See Sec. 4.4.4. The code for the “temporary string” version of string conversion is in a function `tmp_str()`:

```

static int tmp_str(char *sbuf, dptr s, dptr d)
{
  type_case *s of {
    string:
      *d = *s;
    integer: {
      if (Type(*s) == T_Lrgint) {
        word slen, dlen;
        slen = (BlkLoc(*s)->bignumblk.lsd -
              BlkLoc(*s)->bignumblk.msd + 1);
        dlen=slen * NB * 0.3010299956639812; /* 1/log2(10) */
        bigtos(s,d);
      }
      else
        itos(IntVal(*s), d, sbuf);
    }
    real: {
      double res;
      GetReal(s, res);
      rtos(res, d, sbuf);
    }
    cset:
      cston(BlkLoc(*s)->cset.bits, d, sbuf);
    default:

```

```

        return 0;
    }
    return 1;
}

```

If a conversion is required, `itos()`, `rtos()`, or `cstos()` does the actual work, placing its result in `sbuf` and changing the descriptor pointed to by `d` accordingly. These routines return a 1 if the result is a string and a 0 otherwise. The monitoring facilities in Unicon can also report whether no conversion was needed (`E_Nconv`), a conversion was performed successfully (`E_Sconv`), or the conversion failed (`E_Fconv`).

If a converted string is in a buffer that is local to the calling routine, it must be copied into allocated storage, or it would be destroyed when that routine returns. The fully general version of `cnv_str()` is equivalent to the following function. Because this function is heavily called, in reality the body of `tmp_str()` is inlined in `cnv_str()`.

```

int cnv_str(dptr s, dptr d)
{
    char sbuf[MaxCvtLen];

    type_case *s of {
        string: {
            *d = *s;
            return 1;
        }
        default: {
            if (!tmp_str(sbuf, s, d)) return 0;
        }
    }
    Protect(StrLoc(*d) = alcstr(StrLoc(*d), StrLen(*d)), fatalerr(0, NULL));
    return 1;
}

```

## 12.2 Dereferencing and Assignment

If there were no trapped or keyword variables, dereferencing and assignment would be trivial. For example, the descriptor `d` is dereferenced by

```
d = *VarLoc(d)
```

where `VarLoc` references the v-word of `d`:

```
#define VarLoc(d) ((d).vword.dptr)
```

The dereferencing or assignment to a trapped variable, on the other hand, may involve a complicated computation. This computation reflects the meaning associated with the operation on the source-language expression that is represented in the implementation as a trapped variable. For example, as discussed previously, in

```
x[y] := z
```

the value of *x* may be a list, a string, a table, or a record. A subscripted list or record does not produce a trapped variable, but the other two cases do. For a string, the variable on the left side of the assignment is a substring trapped variable. For a table, the variable is a table-element trapped variable. In the first case, the assignment involves the concatenation of three strings and the assignment of the result to *x*. In the second case, it involves looking for *y* in the table. If there is a table element for *y*, its assigned value is changed to the value of *z*. Otherwise, the table-element trapped-variable block is converted to a table-element block with the assigned value, and the block is inserted in the appropriate chain.

### 12.2.1 Dereferencing

Dereferencing of other trapped variables involves computations of comparable complexity. Dereferencing is done in the interpreter loop for arguments of operators for which variables are not needed. For example, in

```
n+m
```

the identifiers *n* and *m* are dereferenced before the function for addition is called (See Sec. 8.3.1). On the other hand, in

```
s[i]
```

the identifier *i* is dereferenced, but *s* is not, since the subscripting routine needs the variable as well as its value.

The function invocation routine also dereferences variables before a function is called. Note that there is no function that requires an argument that is a variable. Suspension and return from procedures also dereference local identifiers and arguments. Dereferencing occurs in a number of other places. For example, the function that handles subscripting must dereference the subscripted variable to determine what kind of result to produce.

The dereferencing routine begins as follows:

```
void deref(s, d)
dptr s, d;
{
/*
* no allocation is done, so nothing need be tended.
```

```

    */
    register union block *bp, **ep;
    struct descrip v;
    int res;

    if (!is:variable(*s)) {
        *d = *s;
    }

```

If *s* does not point to a variable descriptor, the remaining code is skipped.

If *s* points to a variable that is not a trapped variable, dereferencing is simple:

```

    /*
     * An ordinary variable is being dereferenced.
     */
    *d = *(dptr)((word *)VarLoc(*s) + Offset(*s));

```

Otherwise, there are two types of trapped variables with a switch on the type:

```

type_case *s of {
    tvsubs: {
        /*
         * A substring trapped variable is being dereferenced.
         * Point bp to the trapped variable block and v to
         * the string.
         */
        bp = BlkLoc(*s);
        deref(&bp->tvsubs.ssvar, &v);
        if (!is:string(v))
            fatalerr(103, &v);
        if (bp->tvsubs.sspos + bp->tvsubs.sslen - 1 > StrLen(v))
            fatalerr(205, NULL);
        /*
         * Make a descriptor for the substring by getting the
         * length and pointing into the string.
         */
        StrLen(*d) = bp->tvsubs.sslen;
        StrLoc(*d) = StrLoc(v) + bp->tvsubs.sspos - 1;
    }
}

```

```

tvtbl: {
    /*
     * Look up the element in the table.
     */
    bp = BlkLoc(*s);
    ep = memb(bp->tvtbl.clink,&bp->tvtbl.tref,
              bp->tvtbl.hashnum,&res);
    if (res == 1)
        *d = (*ep)->telem.tval; /* found; use value */
    else
        *d = bp->tvtbl.clink->table.defvalue; /* use default */
}

```

A table-element trapped variable may point to a table-element trapped-variable block or to a table-element block. The second situation occurs if two table-element trapped variables point to the same table-element trapped-variable block and assignment to one of the variables converts the table-element trapped-variable block to a table-element block before the second variable is processed. See Sec. 7.2. In this case, the value of the trapped variable is in the table-element block. On the other hand, if the trapped variable points to a table-element trapped-variable block, it is necessary to look up the subscripting value in the table, since an assignment for it may have been made between the time the trapped variable was created and the time it was dereferenced. If it is in the table, the corresponding assigned value is returned. If it is not in the table, the default assigned value is returned.

The last case, keyword variables, is almost the same as for simple variables. These variables impose special semantics on assignment, but not on dereferencing.

```

kywdint:
kywdpos:
kywdsubj:
kywdevent:
kywdwin:
kywdstr:
    *d = *VarLoc(*s);

```

### 12.2.2 Assignment

The values of global identifiers are established initially as a byproduct of reading the icode file into the icode region. When procedures are called, the values of arguments and local identifiers are on the interpreter stack. These operations associate values with variables, but assignment, unlike dereferencing, is explicit in the source program.

The macro GeneralAsgn() is used to perform all such operations. For example, the function for

```

x := y
is
operator{0,1} := asgn(underef x, y)
  if !is:variable(x) then
    runerr(111, x)
  abstract {
    return type(x)
  }
  GeneralAsgn(x, y)
  inline {
    /*
     * The returned result is the variable to which assignment
     * is being made.
     */
    return x;
  }
end

```

Note that assignment may fail. This can occur as the result of an out-of-range assignment to &pos and is indicated by an RTL fail statement from within GeneralAsgn().

Like dereferencing, assignment is trivial for variables that are not trapped. The macro GeneralAsgn() begins as follows:

```

#begdef GeneralAsgn(x, y)
  type_case x of {

```

As for dereferencing, there are two types of trapped variables to be considered. Assignment to a substring trapped variable is rather complicated and deferred to a function subs\_asgn():

```

  tvsubs: {
    abstract {
      store[store[type(x).str_var]] = string
    }
    inline {
      if (subs_asgn(&x, (const dptr)&y) == Error)
        runerr(0);
    }
  }
}

```

The function subs\_asgn():

```

int subs_asgn(dptr dest, const dptr src)
{
    tended struct descrip deststr, srcstr, rsltstr;
    tended struct b_tvsubs *tvsub;

    char *s, *s2;
    word i, len;
    word prelen; /* length of portion of string before substring */
    word poststrt, postlen; /* start and length of portion of
                               string following substring */
    if (!cnv:tmp_string(*src, srcstr))
        ReturnErrVal(103, *src, Error);
    /*
     * Be sure that the variable in the trapped variable points
     * to a string and that the string is big enough to contain
     * the substring.
     */
    tvsub = (struct b_tvsubs *)BlkLoc(*dest);
    deref(&tvsub->ssvar, &deststr);
    if (!is:string(deststr))
        ReturnErrVal(103, deststr, Error);
    prelen = tvsub->sspos - 1;
    poststrt = prelen + tvsub->sslen;
    if (poststrt > StrLen(deststr))
        ReturnErrNum(205, Error);

    /*
     * Form the result string.
     * Start by allocating space for the entire result.
     */
    len = prelen + StrLen(srcstr) + StrLen(deststr) - poststrt;
    Protect(s = alcstr(NULL, len), return Error);
    StrLoc(rsltstr) = s;
    StrLen(rsltstr) = len;
    /*
     * First, copy the portion of the substring string to
     * the left of the substring into the string space.
     */
    s2 = StrLoc(deststr);

```

```

for (i = 0; i < prelen; i++)
    *s++ = *s2++;
/*
 * Copy the string to be assigned into the string space,
 * effectively concatenating it.
 */
s2 = StrLoc(srcstr);
for (i = 0; i < StrLen(srcstr); i++)
    *s++ = *s2++;
/*
 * Copy the portion of the substring to the right of the
 * substring into the string space, completing the result.
 */
s2 = StrLoc(deststr) + poststrt;
postlen = StrLen(deststr) - poststrt;
for (i = 0; i < postlen; i++)
    *s++ = *s2++;

/*
 * Perform the assignment and update the trapped variable.
 */
type_case tvsub->ssvar of {
    kywdevent: {
        *VarLoc(tvsub->ssvar) = rsltstr;
    }
    kywdstr: {
        *VarLoc(tvsub->ssvar) = rsltstr;
    }
    kywdsubj: {
        *VarLoc(tvsub->ssvar) = rsltstr;
        k_pos = 1;
    }
    tvtbl: {
        if (tvtbl_asgn(&tvsub->ssvar, (const dptr)&rsltstr) == Error)
            return Error;
    }
    default: {
        Asgn(tvsub->ssvar, rsltstr);
    }
}

```

```

    }
    tvsub->sslen = StrLen(srcstr);
    return Succeeded;
}

```

Table-element trapped variables are once again deferred in GeneralAsgn() to call to a function, tvtbl\_asgn():

```

tvtbl: {
    abstract {
        store[store[type(x).trpd_tbl].tbl_val] = type(y)
    }
    inline {
        if (tvtbl_asgn(&x, (const dptr)&y) == Error)
            runerr(0);
    }
}

```

Table-element trapped variables have the same possibilities for assignment as for dereferencing. The processing is more complicated, since it may be necessary to convert a table-element trapped-variable block into a table-element block and link it into a chain. Parameters cannot be tended, so their information must be preserved in tended variables before anything is allocated.

```

int tvtbl_asgn(dptr dest, const dptr src)
{
    tended struct b_tvtbl *bp;
    tended struct descrip tval;
    struct b_telem *te;
    union block **slot;
    struct b_table *tp;
    int res;

    /*
     * Allocate table element now (even if we may not need it)
     * because slot cannot be tended. Parameters have to be
     * preserved in tended variables first.
     */
    bp = (struct b_tvtbl *) BlkLoc(*dest);
    tval = *src;

```

```

Protect(te = alctelem(), return Error);

/*
 * First see if reference is in the table; if it is, just
 * update the value. Otherwise, allocate a new table entry.
 */
slot = memb(bp->clink, &bp->tref, bp->hashnum, &res);

if (res == 1) {
    /*
     * Do not need new te, just update existing entry.
     */
    deallocate((union block *) te);
    (*slot)->telem.tval = tval;
}
else {
    /*
     * Link te into table, fill in entry.
     */
    tp = (struct b_table *) bp->clink;
    tp->size++;

    te->clink = *slot;
    *slot = (union block *) te;

    te->hashnum = bp->hashnum;
    te->tref = bp->tref;
    te->tval = tval;

    if (TooCrowded(tp)) /* grow hash table if now too full */
        hgrow((union block *)tp);
}
return Succeeded;
}

```

In the case of a keyword variable, the semantic requirements of the keyword are expressed in the usual mixture of RTL and C, except that type information is guaranteed not to change. The code for &subject is typical:

```

kywdsubj: {

```

```

/*
 * No side effect in the type realm = no abstract clause
 * &subject is still a string and &pos is still an int.
 */
if !cnv:string(y, *VarLoc(x)) then
    runerr(103, y);
inline {
    k_pos = 1;
}
}

```

## 12.3 Input and Output

Icon supports only sequential file access. The run-time system uses C library routines to perform input and output, so the main implementation issues are those that relate to interfacing these routines.

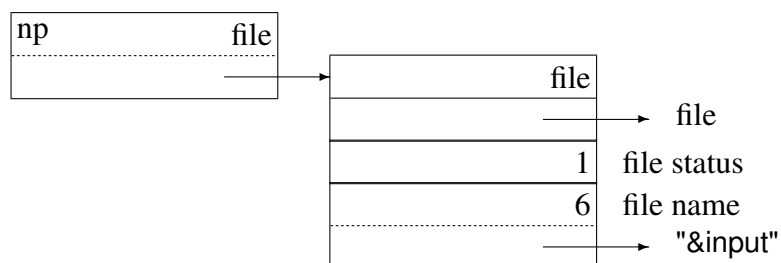

### 12.3.1 Files

A value of type file in Icon points to a block that contains the usual title word, a FILE \* reference to the file, a status word, and the string name of the file. The file status values include

0	closed
1	open for reading
2	open for writing
4	open to create
8	open to append
16	open as a pipe

These decimal numbers correspond to bits in the status word.

For example, the value of &input is

while the value of &output is

Another example is

```
out := open("log", "a")
```

for which the value of `out` is

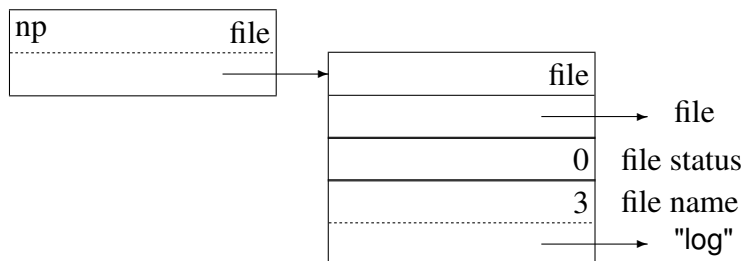

Note that the file status is 10, corresponding to being open for writing and appending.

Closing a file, as in

```
close(out)
```

merely changes its file status:

### 12.3.2 Reading and Writing Data

The function `read(f)` reads a line from the file `f`. In UNIX, a line is just a string of characters up to a newline character. There is no limit on the length of a line and the length of a line cannot be determined before it is read. On the other hand, there must be a place to store the line.

Characters are read into a buffer until a newline character is encountered or the buffer size (by default 512) is reached. A predictive need request is then made to assure that there is enough space in the allocated string region for the string, and the string is copied from the buffer into the string region. This is repeated as needed.

The function `reads(f,i)` reads `i` characters from the file `f`. These characters may include newline characters. There is no limit on `i` other than available memory. A predictive need request can be

made to assure that there is enough space in the allocated string region. Characters are then read directly into the allocated string region without the use of an intervening buffer.

When strings are written, they are written directly from the allocated string region. There is no need to perform any allocation or to use an intermediate buffer.

Several strings can be concatenated on a file by

```
write(s1 , s2, ..., sn)
```

This avoids the internal allocation and concatenation that is required for

```
write(s1 || s2 || ...|| sn)
```

## 12.4 Diagnostic Facilities

Icon's diagnostic facilities consist of

- The function `image(x)`, which produces a string representation of the value of `x`.
- The function `display(f, i)`, which writes the names and values of identifiers in at most `i` levels of procedure call to the file `f`.
- Tracing of procedure calls, returns, resumptions, and suspensions.
- Run-time error termination messages.

Procedure tracing is done in the virtual machine instructions `invoke`, `pret`, `pfail`, and `psusp`. If the value of `&trace` is nonzero, it is decremented and an appropriate trace message is written to standard error output. See Sec. 2.1.12 for an example.

The function `display(f,i)` must locate the names and values of local identifiers and arguments. The names are in the procedure block for the current procedure, which is pointed to by the zeroth argument of the current procedure call. The values are on the interpreter stack as described in Sec. 10.3.3.

Run-time termination messages are produced by the C routine `runerr(n,dp)`, where `dp` is a pointer to the descriptor for the offending value. The value `NULL` is used for `dp` in cases where there is no offending value to print.

In all of these diagnostic situations, string representations of values are needed. The string representation for the "scalar" types `string`, `cset`, `integer`, and `real` is similar to what it is in the text of a source-language program. Long strings and `csets` are truncated to provide output that is easy to read. Other types present a variety of problems. For procedures, the type and procedure name are given.

A list, on the other hand, may be arbitrarily large and may contain values of any type, even lists. While the name may suffice for a procedure, often more information about a list is needed.

As a compromise between information content and readability, only the first three and last three elements of a long list are included in its string representation. Since lists and other non-scalar types may be elements of lists, their representation as elements of a list is more restricted, with only the type and size being shown.

Since trace, display, and error output are written to files, the string representations can be written as they are determined, without regard for how long they are. The function `image(x)`, on the other hand, returns a string value, and space must be allocated for it. A more limited form of string representation is used for non-scalar values, since the space needed might otherwise be very large.

## EXERCISES

**12.1** It is possible to conceive of meaningful ways to convert *any* type of data in Icon to any other. For example, a procedure might be converted to a string that consists of the procedure declaration. How would such a general conversion feature affect the way that types are converted in the run-time system?

**12.2** On computers with 16-bit words, Icon has two representations for integers internally (see Sec. 4.1.3). Describe how this complicates type conversion.

**12.3** How would the addition of a new numeric type, such as complex numbers, affect type conversion?

**12.4** How big would `MaxCvtLen` be if Icon had 512 different characters? 128? 64?

**12.5** List all the source-language operations that perform assignment.

**12.6** Assuming that `x`, `y`, `z`, and `w` all have string values, diagram the structures that are produced in the course of evaluating the following expressions:

```
x[y] := z
z := x[y]
x[y] := z[w]
x[y][z] := w
```

Repeat this exercise for the case where all the identifiers have tables as values.

**12.7** Give an expression in which a table-element trapped variable points to a table-element block rather than to a table-element trapped-variable block.

**12.8** Give an expression in which a table-element trapped variable points to a table-element trapped-variable block, but where there is a table-element block in the table with the same entry value.

**12.9** Why are tended descriptors needed in assignment but not in dereferencing?

**12.10** Show an expression in which, at the end of the case for assignment to a substring trapped variable, the variable to which the assignment is to be made is a trapped variable. Can such a trapped variable be of any of the three types?

**12.11** Why is the string produced by `read(f)` not read directly into the allocated string region?

**12.12** Are there any circumstances in which `write(x1, x2, ..., xn)` requires the allocation of storage?

**12.13** Identify all the portions of blocks for source-language values that are necessary only for diagnostic output. How significant is the amount of space involved?

**12.14** *Question removed: it has been overtaken by subsequent versions after Version 6.*

# **Part II**

## **An Optimizing Compiler for Icon**

by Kenneth W. Walker

## Preface to Part II

There are many optimizations that can be applied while translating Icon programs. These optimizations and the analyses needed to apply them are of interest for two reasons. First, Icon's unique combination of characteristics requires developing new techniques for implementing them. Second, these optimizations are useful in variety of languages and Icon can be used as a medium for extending the state of the art.

Many of these optimizations require detailed control of the generated code. Previous production implementations of the Icon programming language have been interpreters. The virtual machine code of an interpreter is seldom flexible enough to accommodate these optimizations and modifying the virtual machine to add the flexibility destroys the simplicity that justified using an interpreter in the first place. These optimizations can only reasonably be implemented in a compiler. In order to explore these optimizations for Icon programs, a compiler was developed. This part of the compendium describes the compiler and the optimizations it employs. It also describes a run-time system designed to support the analyses and optimizations.

Icon variables are untyped. The compiler contains a type inferencing system that determines what values variables and expression may take on during program execution. This system is effective in the presence of values with pointer semantics and of assignments to components of data structures.

The compiler stores intermediate results in temporary variables rather than on a stack. A simple and efficient algorithm was developed for determining the lifetimes of intermediate results in the presence of goal-directed evaluation. This allows an efficient allocation of temporary variables to intermediate results.

The compiler uses information from type inferencing and liveness analysis to simplify generated code. Performance measurements on a variety of Icon programs show these optimizations to be effective.

The optimizing compiler for Icon was developed by Ken Walker as part of his Ph.D. research, and this part of the Icon/Unicon Compendium is essentially a reprint of his dissertation, which also appeared as University of Arizona CS TR 91-16. Along with his consent, Ken kindly provided the original groff sources to his dissertation. Any typographical and formatting errors that remain are the fault of the editor.

# Chapter 13

## The Optimizing Compiler

Iconc is a practical and complete optimizing compiler for a unique and complex programming language. Part II describes the theory behind several parts of the compiler and describes the implementation of all interesting aspects of the compiler.

### 13.1 Motivation

The motivation for developing a compiler for the Icon programming language is to have a vehicle for exploring optimization techniques. Some performance improvements can be obtained by modifying the run-time system for the language, for example by implementing alternative data structures or storage management techniques. These improvements may apply to a broad class of programs and the techniques can reasonably be implemented in an interpreter system. However, other techniques, such as eliminating unnecessary type checking, apply to expressions within specific programs. The Icon interpreter described in Part I is based on a virtual machine with a relatively small instruction set of powerful operations. A small instruction set is easier to implement and maintain than a large one, and the power of many of the individual operations insures that the overhead of the decoding loop is not excessive. The disadvantage of this instruction set is that an Icon translator that generates code for the interpreter does not have enough flexibility to do many of the possible program-specific optimizations. It is possible to devise a set of more primitive virtual machine instructions that expose more opportunities for these optimizations. Increasingly primitive instruction sets provide increasingly more opportunities for optimizations. In the extreme, the instruction set for a computer (hardware interpreter) can be used and the translator becomes a compiler. A compiler was chosen for this research because it is a good vehicle for exploring program-specific optimizations and eliminates the overhead of a software interpreter which might otherwise become excessive.

## 13.2 Type Inferencing

Most Icon operations require operands with specific types. The types of the actual operands in an expression must be checked and possibly converted to the required types. However, Icon variables are untyped; in general, this checking cannot be done at translation time. The Icon interpreter takes the simple approach to the problem and performs all of the type checking for an expression every time it is executed. For most programs, a *type inferencing system* can provide the information needed to do much of the checking at translation time, eliminating the need for these checks at run time. A type inferencing system determines the types that elements of a program (variables, expression, procedures, etc) can take on at run time. The Icon compiler contains an effective and practical type inferencing system, and implements code generation optimizations that make use of the information produced by the type inferencing system.

Two basic approaches have been taken when developing type inferencing schemes. Schemes based on unification [Milner, smltk type, unify.] construct type signatures for procedures; schemes based on global data flow analysis [typinfer, typcsv, flwanal, progflw.] propagate throughout a program the types variables may take on. One strength of the unification approach is that it is effective at handling polymorphous procedures. Such schemes have properties that make them effective in implementing flexible compile-time type systems. Much of the research on them focuses on this fact. The primary purpose of the type inferencing system for the Icon compiler is to eliminate most of the run-time type checking rather than to report on type inconsistencies at compile time, so these properties have little impact on the choice of schemes used in the compiler. Type inferencing systems based on unification have a significant weakness. Procedure type-signatures do not describe side effects to global variables. Type inferencing schemes based on unification must make crude assumptions about the types of these variables.

Schemes based on global data flow analysis handle global variables effectively. Many Icon programs make significant use of global variables; this is a strong argument in favor of using this kind of type inferencing scheme for Icon. These schemes do a poor job of inferring types in the presence of polymorphous procedures. It is generally too expensive for them to compute the result type of a call in terms of the argument types of that specific call, so result types are computed based on the aggregate types from all calls. Poor type information only results if polymorphism is actually exploited within a program.

The primary use of polymorphous procedures is to implement abstract data types. Icon, on the other hand, has a rich set of built-in data types. While Icon programs make heavy use of these built-in data types and of Icon's polymorphous built-in operations, they seldom make use of user-written polymorphous procedures. While a type inferencing scheme based on global data flow analysis is not effective in inferring the precise behavior of polymorphous procedures, it is effective in utilizing the predetermined behavior of built-in polymorphous operations. These facts combined with the observation that Icon programs often make use of global variables indicate that global data flow analysis is the approach of choice for type inferencing in the Icon compiler.

Icon has several types of non-applicative data structures with pointer semantics. They all can be heterogeneous and can be combined to form arbitrary graphs. An effective type inferencing system must handle these data structures without losing too much information through crude assumptions. These composite data structures typically consist of a few basic elements used repeatedly and they logically have a recursive structure. A number of type inferencing systems handle recursion in applicative data structures [.analrcsv,prlgtyp,typrcsv.]; the system described here handles Icon data types that have pointer semantics and handles destructive assignment to components of data structures. Analyses have been developed to handle pointer semantics for problems such as allocation optimizations and determining pointer aliasing to improve other analyses. However, most of these analyses lose too much information on heterogeneous structures of unbounded depth (such as the mutually referencing syntax trees and symbol tables commonly found in a translator) to be effective type inferencing systems [.progflw,deppttr.].

Work by Chase, Wegman, and Zadeck [.pntstr.] published subsequent to the original technical report on the Icon type inferencing system [.tr88-25.] presents a technique similar to the one used in this type inferencing system. They use a minimal language model to describe the use of the technique for pointer analysis. They speculate that the technique might be too slow for practical use and propose methods of improving the technique in the context of pointer analysis. Use of the prototype Icon type inferencing system described in the original technical report indicates that memory usage is more of a problem than execution time. This problem is addressed in the implementation of type inferencing in the Icon compiler.

### 13.3 Liveness Analysis

Type checking optimizations can be viewed as forms of argument handling optimizations. Other argument handling optimizations are possible. For example, when it is safe to do so, it is more efficient to pass a variable argument by reference than to copy it to a separate location and pass a reference to that location (this particular opportunity for optimization arises because of implementation techniques borrowed from the Icon interpreter – Icon values are larger than pointers and Icon parameter passing is built on top of C parameter passing). Such optimizations are not possible in a stack-based execution model; a temporary-variable model is needed and such a model is used by the Icon compiler. Icon's goal-directed evaluation can extend the lifetime of the intermediate values stored in temporary variables. Icon presents a unique problem in *liveness analysis*, which is the static determination of the lifetime of values in a program [ASU86, progflw.]. While this problem, like other liveness problems, can be solved with traditional techniques, it has enough structure that it can be solved without precomputing a flow graph or using expensive forms of data flow analysis.

The only previous implementation of Icon using a temporary-variable model is a partial implementation by Christopher [.tccompil.]. Christopher uses the fact that Icon programs contain many instances of bounded goal-directed evaluation to deduce limits for the lifetimes of intermediate

values. However, this approach produces a very crude estimate for these lifetimes. While overestimating the lifetime of intermediate values results in a safe allocation of temporary variables to these values, a fine-grained liveness analysis results in the use of fewer temporary variables. The Icon compiler addresses this problem of fine-grained liveness analysis in the presence of goal-directed evaluation and addresses the problem of applying the information to temporary variable allocation.

## 13.4 Analyzing Goal-Directed Evaluation

Many kinds of analyses of Icon programs must deal with Icon's goal-directed evaluation and its unique control structures. These analyses include type inferencing, liveness analysis, and the control flow analyses in O'Bagy's prototype compiler [tr88-31.]. Determining possible execution paths through an Icon program is more complicated than it is for programs written in more conventional languages. The implementation of the type inferencing system and liveness analysis here explore variations on the techniques presented by O'Bagy.

### The Organization of Part II

Part II is logically divided into three subparts. Chapters 14 through 16 present the main ideas upon which the compiler is based, Chapters 17 through 22 describe the implementation of these ideas, and Chapter 23 presents performance measurements of compiled code.

Chapter 14 describes the code generated by the compiler. It explains how Icon data values, variables, and goal-directed evaluation are implemented, independent of the actual translation process. Chapter 15 presents a theoretical model of the type inferencing system used in the compiler. The model includes the important ideas of the type inferencing system, while ignoring some purely pragmatic details. Chapter 16 explains the liveness analysis problem and presents the solution used in the compiler.

The Icon compiler is designed to be a production-quality system. The compiler system consists of the compiler itself and a run-time system. The fact that these two components are not entirely independent must be carefully considered in the design of such a production-quality system. Chapter 17 describes the system as a whole and how the interactions between the components are handled.

Chapter 18 presents the organization of the compiler itself. This chapter describes some parts of the compiler in detail, but defers major topics to other chapters. Chapter 19 builds on the model presented in Chapter 15 and describes the full type inferencing system used in the compiler and its implementation. Chapter 20 describes the translation techniques used to produce code from expressions that employ Icon's goal-directed evaluation scheme and its unique control structures. It also describes the allocation of temporary variables using the information produced by liveness analysis.

The code generator does no look-ahead and as a result it often produces code that is poor when taken in context of subsequent code. This problem is shared with most code generators as are some of the solutions used in this compiler. The unique code generation techniques required by Icon's

goal-directed evaluation produce unusual variations of this problem and require some innovative solutions in addition to the standard ones. Chapter 21 describes the various techniques employed to handle this problem. Chapter 22 describes the optimizations that can be done using the results of type inferencing. These optimizations also make use of liveness information.

Chapter 23 demonstrates the effects of the various optimizations used in the compiler on the performance of specific kinds of expressions. It also presents measurements of the performance of compiled code for a variety of complete programs, comparing the performance to that of the Icon interpreter. In addition, the sizes of the executable code for the complete programs are presented. The conclusions, Chapter 24, summarize what has been done and lists some work that remains to be explored. Chapter 25 describes one successful project to improve the compiler and make it usable on larger programs.

# Chapter 14

## The Translation Model

Modern compilers seldom produce machine code directly. They translate a program into a form closer to machine code than the source language and depend on other tools to finish the translation. If the compiler produces an object module, it depends on a linker and a loader to produce executable code. If the compiler produces assembly language, it also depends on an assembler. A trend among compilers produced in research environments has been to produce C code [.cbook,ansi-c.], adding a C compiler to the list of tools required to finish the translation to machine code [Andrews88, Ramakrishnan, Bartlett 89, Yuasa,Stroustrup,yacc,lex.]. The Icon compiler takes this approach and generates C code.

There are several advantages to compiling a language into C. Low-level problems such as register allocation and the selection and optimization of machine instructions are handled by the C compiler. As long as these problems are outside the scope of the research addressed by the compiler, it is both reasonable and effective to allow another compiler to deal with them. In general, it is easier to generate code in a higher-level language, just as it is easier to program in a higher-level language. As long as the target language lies on a “nearly direct path” from the source language to machine code, this works well. C is closely matched to most modern machine architectures, so few tangential translations must be done in generating C code from Icon.

Another advantage of generating C code is that it greatly increases the portability of the compiler and facilitates cross-compilation. The popularity of C in recent years has resulted in production-quality C compilers for most systems. While the implementation of Icon in C contains some machine and system dependencies, C’s conditional compilation, macro, and file inclusion facilities make these dependencies relatively easy to deal with when they arise. These facts make possible the development of a highly portable Icon compiler, allowing the compiler’s effectiveness to be tested by Icon’s large user community.

## 14.1 Data Representation

Because the target language is C, Icon data must be represented as C data. The careful representation of data and variables is important to the performance of an implementation of a high-level language such as Icon. In addition, information provided by type inferencing can be used to optimize these representations. However, such considerations are largely outside the scope of this current research. For this reason, the representations used in code produced by this compiler and the compiler's run-time system are largely unchanged from those of the Icon interpreter system described in Part I. The interpreter's run-time system is written in C. Therefore borrowing its data representations for the compiler system is simple. This choice of representation means that the run-time system for the compiler could be adapted directly from the run-time system for the interpreter, and it allowed the compiler development to concentrate on parts of the system addressed by this research. In addition, this choice of representation allows a meaningful comparison of the performance of compiled code to the performance of interpreted code.

An Icon value is represented by a two-word descriptor (see Section 4.1). The first word, the *d-word*, contains type information. In the case of a string value, the type is indicated by zero in a high-order bit in the d-word, and the length of a string is stored in low-order bits of the d-word. All other types have a one in that bit and further type information elsewhere in the d-word. The *v-word* of a descriptor indicates the value. The v-word of the null value is zero, the v-word of an Icon integer is the corresponding C integer value, and v-words of other types are pointers to data. A descriptor is implemented with the following C structure:

```
struct descrip {
    word dword; /* type field */
    union {
        word integr; /* integer value */
        char sptr; /* pointer to character string */
        union block bptr; /* pointer to a block */
        dptr descptr; /* pointer to a descriptor */
    } vword;
};
```

word is defined to be a C integer type (one that is at least 32-bits long), block is a union of structures implementing various data types, and dptr is a pointer to a descrip structure.

## 14.2 Intermediate Results

While the representation of data in the compiler is the same as in the interpreter, the method of storing the intermediate results of expression evaluation is not. Two basic approaches have been

used in language implementations to store intermediate results. A stack-based approach is simple and dynamic. It requires no pre-analysis of expressions to allocate storage for the intermediate results, but the simple rigid protocol allows little room for optimization. For Icon there is an additional problem with a stack-based approach. Goal-directed evaluation extends the lifetime of some intermediate results, requiring that the top elements of the evaluation stack be copied at critical points in execution [see Part I, or UA tr88-31]. In spite of the need for this extra copying, most previous implementations of Icon have been implemented with an evaluation stack.

An alternative to using a stack is to pre-allocate a temporary variable for each intermediate result. In this model, operations take explicit locations as arguments. Therefore an operation can directly access program variables as arguments; there is no need to perform the extra operations of pushing addresses or values on a stack. In addition, the lifetime of a temporary variable is not determined by a rigid protocol. The compiler can assign an intermediate result to a temporary variable over an arbitrary portion of the program, eliminating the copying needed to preserve a value beyond the lifetime imposed by a stack-based approach. This compiler uses the temporary-variable model because it allows more opportunities to optimize parameter handling, a major goal of this research.

Icon's automatic storage management dictates the use of a garbage collector in the run-time system. When this garbage collector is invoked, it must be able to locate all values that may be used later in the program. In the interpreter system, intermediate values and local variables are stored on the same stack. The garbage collector sweeps this stack to locate values. In the compiler, a different approach is taken to insure that all necessary values are locatable. Arrays of descriptors are allocated contiguously along with a count of the number of descriptors in the array. The arrays are chained together. An array of descriptors may be local to a C function, or it may be allocated with the malloc library function. The garbage collector locates values by following the chain and scanning the descriptors in each array. These descriptors are referred to as *tended* descriptors.

## 14.3 Executable Code

Even more important than where intermediate results are stored is how they are computed. Some aspects of Icon expression evaluation are similar to those of many other languages, but others aspects are not. Goal-directed evaluation with backtracking poses a particular challenge when implementing Icon expression evaluation. The Icon interpreter is based on a virtual machine that includes backtracking, as are Prolog interpreters based on the Warren Abstract Machine [.wam.]. While details differ between the Icon and Prolog virtual machines, their implementation of control backtracking is based on the same abstract data structures and state variables. Such a virtual machine contains a stack of procedure frames, but the stack is maintained differently from that of a virtual machine that does not implement goal-directed evaluation.

The difference manifests itself when a procedure produces a result, but has alternate results that

it can produce in the event of backtracking. When this occurs, the frame for the procedure remains on the stack after control returns to the caller of the procedure. This frame contains the information needed to produce the alternate results. The left stack in the following diagram shows that procedure *f* has called procedure *g*. The arrows on the left of the stack represent the *backtracking chain* of procedures that can produce alternate results. *bt* points to the head of the backtracking chain which currently starts further down in the stack. The arrows on the right represent the call chain of procedures. *fp* points to the frame of the currently executing procedure.

Figure 14.1: The backtracking chain

Suppose *g* produces the first of several possible results. Execution returns to *f* and *g*'s frame is added to the backtracking chain. This is represented by the middle stack in the diagram. If *f* then calls *h*, its procedure frame is added to the top of the stack as shown in the right stack in the diagram.

If *h* produces a result and is not capable of producing more, execution returns to *f* and the stack again looks like the one in the middle of the diagram (the program pointer within *f* is different, of course). If *h* produces a result and is capable of producing more, execution returns to *f*, but *h*'s frame remains on the stack and is added to the head backtracking chain, similar to what was done when *g* produced a result. If *h* produces no results, backtracking occurs. *h*'s frame is removed from the stack, execution returns to the procedure *g* who's frame is at the head of the backtracking chain, and *g*'s frame is removed from the head of the chain. The stack once again looks like left stack in the diagram and *g* proceeds to produce another result.

Traditional languages such as Pascal or C present high-level virtual machines that contain no notion of backtracking and have no need to perform low-level stack manipulations. Icon expressions with goal-directed evaluation cannot be translated directly into such languages. This is the fundamental problem that must be addressed when designing a compiler for Icon. O'Bagy presents an elegant solution to this problem in her dissertation [tr88-31.]. Her solution is used by this optimizing compiler as a basis for translating Icon expressions into C code. The rest of this section

contains a brief explanation of the variation of her approach that is used in the compiler, while exploring useful ways of viewing the problem. O'Bagy's dissertation describes how control structures not covered in this discussion can be implemented using her model.

Formal semantics is one tool that can be used in understanding a language [gordon denote, stoy.]. The added complexity caused by Icon's goal-directed evaluation is reflected in Gude-  
man's description of Icon using denotational semantics [gudeman denotational.]. While conventional programming languages can be described using one continuation for each expression, Icon requires two continuations. One continuation for an expression embodies the rest of the program if the expression succeeds, while the other embodies the rest of the program if the expression fails.

The Icon compiler uses the notion of success continuations to implement goal-directed evaluation. However, these continuations violate some of the properties traditionally associated with continuations. A continuation in denotational semantics and in the language Scheme [Abelson, [Rees 86].] is a function that never returns. However, the success continuations produced by the compiler implement backtracking by returning. In addition, these continuations implement the rest of the current bounded expression rather than the rest of the entire program. Note that unlike continuations in Scheme, these continuations are created at compile time, not at run time. Some Prolog compilers have been based on a similar continuation-passing technique [Nilsson, Ramakrishnan.].

The C language is oriented toward an imperative style of programming. In order to produce efficient code, the Icon compiler should not generate an excessive number of function calls. Specifically, it should avoid creating continuations for every expression. A more operational view of Icon's semantics and of C's semantics can be useful in understanding how to accomplish this. An operation in Icon can succeed or fail. In the view of denotational semantics, the question of what will be done in each case must be answered, with the answers taking the form of functions. In an operational view, the questions can take the form of where to go in each case. The answers to these questions can be any type of transfer of control supported by the C language: execute the next sequential instruction, execute a function, return from a function, or go to a label.

Most operations in Icon are *monogenic*. That is, they produce exactly one result, like operations in conventional languages. For these operations, the compiler can generate code whose execution simply falls through into the code that implements the subsequent operation.

*Conditional* operations are more interesting. These operations either produce a single value or fail. If such an operation succeeds, execution can fall through into code implementing the subsequent operation. However, if the operation fails, execution must transfer elsewhere in the program. This is accomplished by branching to a *failure label*. If the code for the operation is put in-line, this is straightforward. However, if the operation (either a built-in operation or an Icon procedure) is implemented by a separate C function, the function must notify the caller whether it succeeded or failed and the caller must effect the appropriate transfer of control.

By convention, C functions produced by the compiler and those implementing the run-time routines each return a signal (this convention is violated in some special cases). A signal is an integer (and is unrelated to Unix signals). If one of these C functions needs to return an Icon value,

it does so through a pointer to a result location that is passed to it as an argument. Two standard signals are represented by the manifest constants `A_Continue` and `A_Resume`. A return (either an Icon return expression or the equivalent construct in a built-in operation) is implemented with code similar to

```
*result = operation result;
return A_Continue;
```

Failure is implemented with the code

```
return A_Resume;
```

The code implementing the call of an operation consists of both a C call and signal-handling code.

```
switch (operation(args, &result)) {
    case A_Continue: break;
    case A_Resume: goto failure label;
}
```

This code clearly can be simplified. This form is general enough to handle the more complex signal handling that can arise during code generation. Simplifying signal handling code is described in Chapter 21.

Generators pose the real challenge in implementing Icon. A generator includes code that must be executed if subsequent failure occurs. In addition, a generator, in general, needs to retain state information between suspending and being resumed. As mentioned above, this is accomplished by calling a success continuation. The success continuation contains subsequent operations. If an operation in the continuation fails, an `A_Resume` signal is returned to the generator, which then executes the appropriate code. The generator retains state information in local variables. If the generator is implemented as a C function, a pointer to the continuation is passed to it. Therefore, a function implementing a generative operation need not know its success continuation until run time.

Consider the operation `i to j`. This operation can be implemented in Icon with a procedure like

```
procedure To(i, j)
    while i <= j do {
        suspend i
        i += 1
    }
    fail
end
```

It can be implemented by an analogous C function similar to the following (for simplicity, C ints are used here instead of Icon values).

```
int to(i, j, result, succ_cont)
    int i, j;
    int *result;
    int (*succ_cont)();
{
    int signal;

    while (i <= j) {
        *result = i;
        signal = (*succ_cont)();
        if (signal != A_Resume)
            return signal;
        ++i;
    }
    return A_Resume;
}
```

There is no explicit failure label in this code, but it is possible to view the code as if an implicit failure label occurs before the ++i.

The Icon expression

every write(1 to 3)

can be compiled into the following code (for simplicity, the write function has been translated into printf and scoping issues for result have been ignored). Note that the every simply introduces failure.

```
switch (to(1, 3, &result, sc)) { /* standard signal-handling code */
    ...
}

int sc() {
    printf("%d\n", result);
    return A_Resume;
}
```

The final aspect of Icon expression evaluation that must be dealt with is that of bounded expressions. Once execution leaves a bounded expression, that expression cannot be resumed. At this point, the state of the computation with respect to backtracking looks as it did when execution entered the bounded expression. This means that, in generated code, where to go on failure (either by branching to an explicit failure label or by returning an `A_Resume` signal) must be the same. However, this failure action is only correct in the C function containing the start of the code for the bounded expression. If a function suspended by calling a success continuation, execution is no longer in that original C function. To accommodate this restoration of failure action, execution must return to that original function.

This is accomplished by setting up a *bounding label* in the original C function and allocating a signal that corresponds to the label. When the end of the bounded expression is reached, the signal for the bounding label is returned. When the signal reaches the function containing the label, it is converted into a `goto`. It can be determined statically which calls must convert which signals. Note that if the bounded expression ends in the original C function, the “return signal” is already in the context of the label. In this case, it is immediately transformed into a `goto` by the compiler, and there is no real signal handling.

Consider the Icon expression

```
move(1);
...
```

The `move` function suspends and the C function implementing it needs a success continuation. In this case, `move` is called in a bounded context, so the success continuation must return execution to the function that called `move`. The continuation makes use of the fact that, like the C function for `to`, the one for `move` only intercepts `A_Resume` signals and passes all other signals on to its caller.

This expression can be implemented with code similar to the following. There are two possible signals that might be returned. `move` itself might produce an `A_Resume` signal or it might pass along the bounding signal from the success continuation. Note that for a compound expression, both the bounding label and the failure label are the same. In general, this is not true. In this context, the result of `move(1)` is discarded. The variable `trashcan` receives this value; it is never read.

```
switch (move(1, &trashcan, sc)) {
    case 1:
        goto L1;
    case A_Resume:
        goto L1;
}
L1: /* bounding label & failure label */
```

```

...

int sc() {
    return 1; /* bound signal */
}

```

### Calling Conventions

This discussion has touched on the subject of calling conventions for run-time routines. In Icon, it is, in general, impossible to know until run time what an invocation is invoking. This is handled in the compiler with a standard calling convention for the C functions implementing operations and procedures. This calling convention allows a C function to be called without knowing anything about the operation it implements.

A function conforming to the standard calling convention has four parameters. These parameters are, in order of appearance, the number of Icon arguments (a C int), a pointer to the beginning of an array of descriptors holding the Icon arguments, a pointer to the descriptor used as the Icon result location, and a success continuation to use for suspension. The function itself is responsible for any argument conversions including dereferencing, and for argument list adjustment. As explained above, the function returns an integer signal. The function is allowed to return the signals `A_Resume`, `A_Continue`, and any signals returned by the success continuation. It may ignore the success continuation if it does not suspend. The function may be passed a null continuation. This indicates that the function will not be resumed. In this case, `suspend` acts like a simple return, passing back the signal `A_Continue` (this is not shown in the examples). The outline of a standard-conforming function is

```

int function-name(nargs, args, result, succ_cont)
int nargs; dptr args; dptr result;
continuation succ_cont;
{
    ...
}

```

continuation is defined to be a pointer to a function taking no arguments and returning an integer.

Later sections of this dissertation describe the code generation process in more detail and describe optimizations of various parts of the code including parameter passing, continuations, signal handling, and branching.

# Chapter 15

## The Type Inferencing Model

Three sections of this dissertation are devoted to type inferencing: two chapters and an appendix. This chapter develops a theoretical model of type inferencing for Icon. For simplicity, it ignores some features of the language. This chapter presents intuitive arguments for the correctness of the formal model. Chapter 19 describes the actual implementation of type inferencing in the Icon compiler. The implementation handles the full Icon language and, for pragmatic reasons, differs from the theoretical model in some details.

This chapter starts with the motivation for performing type inferencing. It then describes the concept of *abstract interpretation*. This concept is used as a tool in this chapter to develop a type inferencing system from Icon's semantics. This chapter gives an intuitive presentation of this development process before presenting the formal models of abstract semantics for Icon. The most abstract of the formal models is the type inferencing system.

### 15.1 Motivation

Variables in the Icon programming language are untyped. That is, a variable may take on values of different types as the execution of a program proceeds. In the following example, `x` contains a string after the read (if the read succeeds), but it is then assigned an integer or real, provided the string can be converted to a numeric type.

```
x := read()
if numeric(x) then x +:= 4
```

In general, it is impossible to know the type of an operator's operands at translation time, so some type checking must be done at run time. This type checking may result in type conversions, run-time errors, or the selection among polymorphous operations (for example, the selection of

integer versus real addition). In the Icon interpreter system, all operators check all of their operands at run time. This incurs significant overhead.

Much of this run-time type checking is unnecessary. An examination of typical Icon programs reveals that the types of most variables remain consistent throughout execution (except for the initial null value) and that these types can often be determined by inspection. Consider

```
if x := read() then
    y := x || ";"
```

Clearly both operands of `||` are strings so no checking or conversion is needed.

The goal of a type inferencing system is to determine what types variables may take on during the execution of a program. It associates with each variable usage a set of the possible types of values that variable might have when execution reaches the usage. This set may be a conservative estimate (overestimate) of the actual set of possible types that a variable may take on because the actual set may not be computable, or because an analysis to compute the actual set may be too expensive. However, a good type inferencing system operating on realistic programs can determine the exact set of types for most operands and the majority of these sets in fact contain single types, which is the information needed to generate code without type checking. The Icon compiler has an effective type inferencing system based on data flow analysis techniques.

## 15.2 Abstract Interpretation

Data flow analysis can be viewed as a form of abstract interpretation [absintrp.]. This can be particularly useful for understanding type inferencing. A “concrete” interpreter for a language implements the standard (operational) semantics of the language, producing a sequence of states, where a state consists of an execution point, bindings of program variables to values, and so forth. An abstract interpreter does not implement the semantics, but rather computes information related to the semantics. For example, an abstract interpretation may compute the sign of an arithmetic expression rather than its value. Often it computes a “conservative” estimate for the property of interest rather than computing exact information. Data flow analysis is simply a form of abstract interpretation that is guaranteed to terminate. This chapter presents a sequence of approximations to Icon semantics, culminating in one suitable for type inferencing.

Consider a simplified operational semantics for Icon, consisting only of program points (with the current execution point maintained in a program counter) and variable bindings (maintained in an environment). As an example of these semantics, consider the following program. Four program points are annotated with numbers using comments (there are numerous intermediate points not annotated).

```

procedure main()
local s, n

# 1:
s := read()
# 2:
every n := 1 to 2 do {
  # 3:
  write(s[n])
}
# 4:
end

```

If the program is executed with an input of *abc*, the following states are included in the execution sequence (only the annotated points are listed). States are expressed in the form *program point: environment*.

```

1: [s = null, n = null]
2: [s = "abc", n = null]
3: [s = "abc", n = 1]
3: [s = "abc", n = 2]
4: [s = "abc", n = 2]

```

It is customary to use the *collecting semantics* of a language as the first abstraction (approximation) to the standard semantics of the language. The collecting semantics of a program is defined in Cousot and Cousot [.absintrp.] (they use the term *static semantics*) to be an association between program points and the sets of environments that can occur at those points during all possible executions of the program.

Once again, consider the previous example. In general, the input to the program is unknown, so the read function is assumed to be capable of producing any string. Representing this general case, the set of environments (once again showing only variable bindings) that can occur at point 3 is

```

[s = "", n = 1],
[s = "", n = 2],
[s = "a", n = 1],
[s = "a", n = 2],
...
[s = "abcd", n = 1],

```

```
[s = "abcd", n = 2],
...
```

A type inferencing abstraction further approximates this information, producing an association between each variable and a type at each program point. The actual type system chosen for this abstraction must be based on the language and the use to which the information is put. The type system used here is based on Icon's run-time type system. For structure types, the system used retains more information than a simple use of Icon's type system would retain; this is explained in detail later. For atomic types, Icon's type system is used as is. For point 3 in the preceding example the associations between variables and types are

```
[s = string, n = integer]
```

The type inferencing system presented in this chapter is best understood as the culmination of a sequence of abstractions to the semantics of Icon, where each abstraction discards certain information. For example, the collecting semantics discards sequencing information among states; in the preceding program, collecting semantics determine that, at point 3, states may occur with  $n$  equal to 1 and with  $n$  equal to 2, but does not determine the order in which they must occur. This sequencing information is discarded because desired type information is a static property of the program.

The first abstraction beyond the collecting semantics discards dynamic control flow information for goal directed evaluation. The second abstraction collects, for each variable, the value associated with the variable in each environment. It discards information such as, "x has the value 3 when y has the value 7", replacing it with "x may have the value 3 sometime and y may have the value 7 sometime.". It effectively decouples associations between variables.

This second abstraction associates a set of values with a variable, but this set may be any of an infinite number of sets and it may contain an infinite number of values. In general, this precludes either a finite computation of the sets or a finite representation of them. The third abstraction defines a type system that has a finite representation. This abstraction discards information by increasing the set associated with a variable (that is, making the set less precise) until it matches a type. This third model can be implemented with standard iterative data flow analysis techniques.

This chapter assumes that an Icon program consists of a single procedure and that all invocations are to built-in functions. It also assumes that there are no co-expressions beyond the main co-expression. See Chapter 19 for information on how to extend the abstractions to multiple procedures and multiple co-expressions.

## 15.3 Collecting Semantics

The collecting semantics of an Icon program is defined in terms of a *flow graph* of the program. A flow graph is a directed graph used to represent the flow of control in a program. Nodes in the graph represent the executable primitives in the program. An edge exists from node **A** to node **B** if it is possible for execution to pass directly from the primitive represented by node **A** to the primitive represented by node **B**. Cousot and Cousot [.absintrap.] prove that the collecting semantics of a program can be represented as the least fixed point of a set of equations defined over the edges of the program's flow graph. These equations operate on sets of environments.

For an example of a flow graph, consider the Icon program

```
procedure main()
  every write(1 to 3)
end
```

The diagram below on the left shows the abstract syntax tree for this procedure, including the implicit fail at the end of the procedure. The invoke node in the syntax tree represents procedure invocation. Its first argument must evaluate to the procedure to be invoked; in this case the first argument is the global variable write. The rest of the arguments are used as the arguments to the procedure. pfail represents procedure failure (as opposed to expression failure within a procedure). Nodes corresponding to operations that produce values are numbered for purposes explained below.

A flow graph can be derived from the syntax tree. This is shown on the right.

Figure 15.1: Syntax tree and flow graph for a simple procedure

The node labeled procedure main is the *start node* for the procedure; it performs any necessary initializations to establish the execution environment for the procedure. The edge from invoke to to

is a resumption path induced by the control structure every. The path from to to pfail is the failure path for to. It is a forward execution path rather than a resumption path because the compound expression (indicated by ;) limits backtracking out of its left-hand sub-expression. Chapter 19 describes how to determine the edges of the flow graph for an Icon program.

Both the standard semantics and the abstract semantics must deal with the intermediate results of expression evaluation. A temporary-variable model is used because it is more convenient for this analysis than a stack model. This decision is unrelated to the use of a temporary-variable model in the compiler. This analysis uses a trivial assignment of temporary variables to intermediate results. Temporary variables are not reused. Each node that produces a result is assigned some temporary variable  $ri$  in the environment. Assuming that temporary variables are assigned to the example according to the node numbering, the to operation has the effect of

$$r3 := r4 \text{ to } r5$$

Expressions that represent alternate computations must be assigned the same temporary variable, as in the following example for the subexpression  $x := ("a" \mid "b")$ . The syntax tree below on the left and the flow graph are shown on the right.

Figure 15.2: syntax tree and flow graph for  $x := ("a" \mid "b")$

The if and case control structures are handled similarly. In addition to temporary variables for intermediate results, some generators may need additional temporary variables to hold internal states during suspension. It is easy to devise a scheme to allocate them where they are needed; details are not presented here. The syntax tree is kept during abstract interpretation and used to determine the temporary variables associated with an operation and its operands.

The equations that determine the collecting semantics of the program are derived directly from the standard semantics of the language. The set of environments on an edge of the flow graph is related to the sets of environments on edges coming into the node at the head of this edge. This relationship is derived by applying the meaning of the node (in the standard semantics) to each of the incoming environments.

It requires a rather complex environment to capture the full operational semantics (and collecting semantics) of a language like Icon. For example, the environment needs to include a representation of the external file system. However, later abstractions only use the fact that the function `read` produces strings. This discussion assumes that it is possible to represent the file system in the environment, but does not give a representation. Other complexities of the environment are discussed later. For the moment, examples only show the bindings of variables to unstructured (atomic) values.

As an example of environments associated with the edges of a flow graph, consider the assignment at the end of the following code fragment. The comments in the `if` expression are assertions that are assumed to hold at those points in the example.

```

if x = 7 then {
    ...
    # x is 7 and y is 3
}
else {
    ...
    # (x is null and y is 1) or (x is "abc" and y is 2)
}
x := y + 2

```

Because of the preceding `if` expression, there are two paths reaching the assignment. The diagram below shows the flow graph and accompanying environments for the expression; the diagram ignores the fact that the assignment expression requires several primitive operations to implement.

Figure 15.3: A flow graph for `x := y + 2`

For a conditional expression, an incoming environment is propagated to the path that it would cause execution to take in the standard semantics. This requires distinguishing the paths to be taken on failure (backtracking paths) from those to be taken on success. The following diagram shows an example of this.

Figure 15.4: A flow graph for a conditional expression

In general there may be several possible backtracking paths. The environments in the standard and collecting semantics need to include a stack of current backtracking points and control flow information, and the flow graph needs instructions to maintain this stack. The Icon interpreter system described in Part I is an example of how this information can be maintained. However, the first abstraction to the collecting semantics eliminates the need for this information, so the information is not presented in detail here.

## Model 1: Eliminating Control Flow Information

The first abstraction involves taking the union of the environments propagated along all the failure paths from a node in the collecting semantics and propagating that union along each of the failure paths in the new abstraction. This abstraction eliminates the stack of backtracking points from the environment.

A more formal definition for this model requires taking a closer look at Icon data values, especially those values with internal structure. In order to handle Icon data objects with pointer semantics, an environment needs more than variable bindings. This fact is important to type inferencing. The problem is handled by including two components in the environment. The first is the *store*, which maps variables to values. Variables include *named* variables, *temporary* variables, and *structure* variables. Named variables correspond to program identifiers. Temporary variables hold intermediate results as discussed above. Structure variables are elements of structures such as lists. Note that the sets of named variables and temporary variables are each finite (based on the assumption that a program consists of a single non-recursive procedure; as mentioned earlier, this assumption is removed in Chapter 19), but for some non-terminating programs, the set of structure variables may be infinite. *Program* variables include both named variables and structure variables but not temporary variables.

Values include atomic data values such as integers, csets, and strings. They also include *pointers* that reference objects with pointer semantics. In addition to the values just described, temporary variables may contain references to program variables. These *variable references* may be used

by assignments to update the store or they may be dereferenced by other operations to obtain the values stored in the variables.

The second part of the environment is the *heap*. It maps pointers to the corresponding data objects (this differs from the heap in the Icon implementation in that that heap also contains some data objects that do not have pointer semantics). For simplicity, the only data type with pointer semantics included in this discussion is the list. A list is a partial mapping from integers to variables. Representing other data types with pointer semantics is straightforward; this is discussed in Chapter 19.

The first abstraction is called Model 1. The notations  $\text{envir}_{[n]}$ ,  $\text{store}_{[n]}$ , and  $\text{heap}_{[n]}$  refer to the sets of possible environments, stores, and heaps respectively in model  $n$ . For example,  $\text{envir}_{[1]}$  is the set of possible environments in the first abstraction. In the following set of definitions,  $X \times Y$  is the set of ordered pairs where the first value in the pair is from  $X$  and the second value is from  $Y$ .  $X \rightarrow Y$  is the set of partial functions from  $X$  to  $Y$ . The definition of the set of possible environments for model 1 is

$$\begin{aligned}\text{envir}_{[1]} &= \text{store}_{[1]} \times \text{heap}_{[1]} \\ \text{store}_{[1]} &= \text{variables} \rightarrow \text{values} \\ \text{values} &= \text{integers} \cup \text{strings} \cup \dots \cup \text{pointers} \cup \text{variables} \\ \text{heap}_{[1]} &= \text{pointers} \rightarrow \text{lists, where lists} = \text{integers} \rightarrow \text{variables}\end{aligned}$$

For example, the expression

**a := ["abc"]**

creates a list of one element whose value is the string `abc` and assigns the list to the variable `a`. Let  $p_1$  be the pointer to the list and let  $v_1$  be the (anonymous) variable within the list. The resulting environment,  $e \in \text{envir}_{[1]}$ , might be

$$\begin{aligned}e &= (s, h), \text{ where } s \in \text{store}_{[1]}, h \in \text{heap}_{[1]} \\ s(a) &= p_1 \\ s(v_1) &= \text{"abc"}\end{aligned}$$

$$h(p_1) = L_1, \text{ where } L_1 \in \text{lists}$$

$$L_1(1) = v_1$$

If the statement

**a[1] := "xyz"**

is executed, the subscripting operation dereferences `a` producing  $p_1$ , then uses the heap to find  $L_1$ , which it applies to 1 to produce the result  $v_1$ . The only change in the environment at this point is to temporary variables that are not shown. The assignment then updates the store, producing

$$\begin{aligned}
e_1 &= (s_1, h) \\
s_1(a) &= p_1 \\
s_1(v_1) &= \text{"xyz"}
\end{aligned}$$

Assignment does not change the heap. On the other hand, the expression

`put(a, "xyz")`

adds the string xyz to the end of the list; if it is executed in the environment  $e$ , it alters the heap along with adding a new variable to the store.

$$\begin{aligned}
e_1 &= (s_1, h_1) \\
s_1(a) &= p_1 \\
s_1(v_1) &= \text{"abc"} \\
s_1(v_2) &= \text{"xyz"} \\
h_1(p_1) &= L_2 \\
L_2(1) &= v_1 \\
L_2(2) &= v_2
\end{aligned}$$

If a formal model were developed for the collecting semantics, it would have an environment similar to the one in Model 1. However, it would need a third component with which to represent the backtracking stack.

## Model 2: Decoupling Variables

The next approximation to Icon semantics, Model 2, takes all the values that a variable might have at a given program point and gathers them together. In general, a variable may have the same value in many environments, so this, in some sense, reduces the amount of space required to store the information (though the space may still be unbounded). The “cost” of this reduction of storage is that any information about relationship of values between variables is lost.

Model 2 is also defined in terms of environments, stores, and heaps, although they are different from those of Model 1. A store in Model 2 maps sets of variables to sets of values; each resulting set contains the values associated with the corresponding variables in environments in Model 1. Similarly, a heap in Model 2 maps sets of pointers to sets of lists; each of these sets contains the lists associated with the corresponding pointers in environments in Model 1. An environment in Model 2 contains a store and a heap, but unlike in Model 1, there is only one of these environments associated with each program point. The environment is constructed so that it effectively “contains” the environments in the set associated with the point in Model 1.

The definition of Model 2 is

$$\begin{aligned}
\text{envir}_{[2]} &= \text{store}_{[2]} \times \text{heap}_{[2]} \\
\text{store}_{[2]} &= 2^{\text{variables}} \rightarrow 2^{\text{values}} \\
\text{heap}_{[2]} &= 2^{\text{pointers}} \rightarrow 2^{\text{lists}}
\end{aligned}$$

In Model 1, operations produce elements from the set *values*. In Model 2, operations produce subsets of this set. It is in this model that *read* is taken to produce the set of all strings and that the existence of an external file system can be ignored.

Suppose a program point is annotated with the set containing the following two environments from Model 1.

$$\begin{aligned}
e_1, e_2 &\in \text{envir}_{[1]} \\
e_1 &= (s_1, h_1) \\
s_1(x) &= 1 \\
s_1(y) &= p_1 \\
h_1(p_1) &= L_1 \\
\\ 
e_2 &= (s_2, h_2) \\
s_2(x) &= 2 \\
s_2(y) &= p_1 \\
h_2(p_1) &= L_2
\end{aligned}$$

Under Model 2 the program point is annotated with the single environment  $\hat{e} \in \text{envir}_{[2]}$ , where

$$\begin{aligned}
\hat{e} &= (\hat{s}, \hat{h}) \\
\hat{s}(\{x\}) &= \{1, 2\} \\
\hat{s}(\{y\}) &= \{p_1\} \\
\hat{s}(\{x, y\}) &= \{1, 2, p_1\} \\
\hat{h}(\{p_1\}) &= \{L_1, L_2\}
\end{aligned}$$

Note that a store in Model 2 is distributive over union. That is,

$$\hat{s}(X \cup Y) = \hat{s}(X) \cup \hat{s}(Y)$$

so listing the result of  $\hat{s}(\{x, y\})$  is redundant. A heap in Model 2 also is distributive over union.

In going to Model 2 information is lost. In the last example, the fact that  $x = 1$  is paired with  $p_1 = L_1$  and  $x = 2$  is paired with  $p_1 = L_2$  is not represented in Model 2.

Just as *read* is extended to produce a set of values, so are all other operations. These "extended" operations are then used to set up the equations whose solution formally defines Model 2. This extension is straightforward. For example, the result of applying a unary operator to a set is the set

obtained by applying the operator to each of the elements in the operand. The result of applying a binary operator to two sets is the set obtained by applying the operator to all pairs of elements from the two operands. Operations with more operands are treated similarly. For example

$$\begin{aligned}\{1, 3, 5\} + \{2, 4\} &= \{1 + 2, 1 + 4, 3 + 2, 3 + 4, 5 + 2, 5 + 4\} \\ &= \{3, 5, 5, 7, 7, 9\} \\ &= \{3, 5, 7, 9\}\end{aligned}$$

The loss of information mentioned above affects the calculation of environments in Model 2. Suppose the addition in the last example is from

$$z := x + y$$

and that Model 1 has the following three environments at the point before the calculation

$$\begin{aligned}[x = 1, y = 2, z = 0] \\ [x = 3, y = 2, z = 0] \\ [x = 5, y = 4, z = 0]\end{aligned}$$

After the calculation the three environments will be

$$\begin{aligned}[x = 1, y = 2, z = 3] \\ [x = 3, y = 2, z = 5] \\ [x = 5, y = 4, z = 9]\end{aligned}$$

If these latter three environments are translated into an environment of Model 2, the result is

$$[x = \{1, 3, 5\}, y = \{2, 4\}, z = \{3, 5, 9\}]$$

However, when doing the computation using the semantics of  $+$  in Model 2, the value for  $z$  is  $\{3, 5, 7, 9\}$ . The solution to the equations in Model 2 overestimates (that is, gives a conservative estimate for) the values obtained by computing a solution using Model 1 and translating it into the domain of Model 2.

Consider the following code with respect to the semantics of assignment in Model 2. (Assume that the code is executed once, so only one list is created.)

```

x := [10, 20]
i := if read() then 1 else 2
x[i] := 30

```

After the first two assignments, the store maps  $x$  to a set containing one pointer and maps  $i$  to a set containing 1 and 2. The third assignment is not as straightforward. Its left operand evaluates to two variables; the most that can be said about one of these variables after the assignment is that it might have been assigned 30. If  $(s, h)$  is the environment after the third assignment then

$$\begin{aligned}
 s(\{x\}) &= \{p_1\} \\
 s(\{i\}) &= \{1, 2\} \\
 s(\{v_1\}) &= \{10, 30\} \\
 s(\{v_2\}) &= \{20, 30\}
 \end{aligned}$$

$$h(\{p_1\}) = \{L_1\}$$

$$\begin{aligned}
 L_1(1) &= v_1 \\
 L_1(2) &= v_2
 \end{aligned}$$

Clearly all assignments could be treated as *weak updates* [.pntstr.], where a weak update is an update that may or may not take place. However, this would involve discarding too much information; assignments would only add to the values associated with variables and not replace the values. Therefore assignments where the left hand side evaluates to a set containing a single variable are treated as special cases. These are implemented as *strong updates*.

## Model 3: A Finite Type System

The environments in Model 2 can contain infinite amounts of information, as in the program

```

x := 1
repeat x += 1

```

where the set of values associated with  $x$  in the loop consists of all the counting numbers. Because equations in Model 2 can involve arbitrary arithmetic, no algorithm can find the least fixed point of an arbitrary set of these equations.

The final step is to impose a finitely representable type system on values. A type is a (possibly infinite) set of values. The type system presented here includes three classifications of basic types.

The first classification consists of the Icon types without pointer semantics: integers, strings, csets, etc. The second classification groups pointers together according to the lexical point of their creation. This is similar to the method used to handle recursive data structures in Jones and Muchnick [analrcsv.]. Consider the code

```
every insert(x, [1 to 5])
```

If this code is executed once, five lists are created, but they are all created at the same point in the program, so they all belong to the same type. The intuition behind this choice of types is that structures created at the same point in a program are likely to have components of the same type, while structures created at different points in a program may have components of different types.

The third classification of basic types handles variable references. Each named variable and temporary variable is given a type to itself. Therefore, if *a* is a named variable, {*a*} is a type. Structure variables are grouped into types according to the program point where the pointer to the structure is created. This is not necessarily the point where the variable is created; in the following code, a pointer to a list is created at one program point, but variables are added to the list at different points

```
x := []
push(x, 1)
push(x, 2)
```

References to these variables are grouped into a type associated with the program point for [], not the point for the corresponding push.

If a program contains *k* non-structure variables and there are *n* locations where pointers can be created, then the basic types for the program are integer, string, ...,  $P_1$ , ...,  $P_n$ ,  $V_1$ , ...,  $V_n$ ,  $\{v_1\}$ , ...,  $\{v_k\}$  where  $P_i$  is the pointer type created at location *i*,  $V_i$  is the variable type associated with  $P_i$ , and  $v_i$  is a named variable or a temporary variable. Because programs are lexically finite they each have a finite number of basic types. The set of all types for a program is the smallest set that is closed under union and contains the empty set along with the basic types:

$$\text{types} = \{ \{ \}, \text{integers, strings, ...}, (\text{integers} \cup \text{strings}), \dots, (\text{integers} \cup \text{strings} \cup \dots \cup \{v_k\}) \}$$

Model 3 replaces the arbitrary sets of values of Model 2 by types. This replacement reduces the precision of the information, but allows for a finite representation and allows the information to be computed in finite time.

In Model 3, both the store and the heap map types to types. This store is referred to as the *type store*. The domain of type store is *variable types*, that is, those types whose only values are variable references. Similarly, the domain of the heap is *pointer types*. Its range is the set types containing only structure variables. A set of values from Model 2 is converted to a type in Model 3 by mapping that set to the smallest type containing it. For example, the set

$\{1, 4, 5, "23", "0"\}$   
is mapped to

$$\text{integer} \cup \text{string}$$

The definition of  $\text{envir}_{[3]}$  is

$$\begin{aligned}\text{envir}_{[3]} &= \text{store}_{[3]} \times \text{heap}_{[3]} \\ \text{store}_{[3]} &= \text{variable-types} \rightarrow \text{types} \\ \text{heap}_{[3]} &= \text{pointer-types} \rightarrow \text{structure-variable-types} \\ \text{types} &\subseteq 2^{\text{values}} \\ \text{variable-types} &\subseteq \text{types} \\ \text{structure-variable-types} &\subseteq \text{variable-types} \\ \text{pointer-types} &\subseteq \text{types}\end{aligned}$$

There is exactly one variable type for each pointer type in this model. The heap simply consists of this one-to-one mapping; the heap is of the form

$$h(\mathbf{P}_i) = \mathbf{V}_i$$

This mapping is invariant over a given program. Therefore, the type equations for a program can be defined over  $\text{store}_{[3]}$  rather than  $\text{envir}_{[3]}$  with the heap embedded within the type equations.

Suppose an environment from Model 2 is

$$\begin{aligned}e &\in \text{envir}_{[2]} \\ e &= (s, h)\end{aligned}$$

$$\begin{aligned}s(\{\mathbf{a}\}) &= \{p_1, p_2\} \\ s(\{v_1\}) &= \{1, 2\} \\ s(\{v_2\}) &= \{1\} \\ s(\{v_3\}) &= \{12.03\}\end{aligned}$$

$$\begin{aligned}h(\{p_1\}) &= \{L_1, L_2\} \\ h(\{p_2\}) &= \{L_3\}\end{aligned}$$

$$L_1(1) = v_1$$

$$L_2(1) = v_1$$

$$L_2(2) = v_2$$

$$L_3(1) = v_3$$

Suppose the pointers  $p_1$  and  $p_2$  are both created at program point 1. Then the associated pointer type is  $P_1$  and the associated variable type is  $V_1$ . The corresponding environment in Model 3 is

$$\begin{aligned}\hat{e} &\in \mathbf{envir}_{[3]} \\ \hat{e} &= (\hat{s}, \hat{h}) \\ \hat{s}(\{\mathbf{a}\}) &= P_1 \\ \hat{s}(V_1) &= \text{integer} \cup \text{real} \\ \hat{h}(P_1) &= V_1\end{aligned}$$

The collecting semantics of a program establishes a set of (possibly) recursive equations between the sets of environments on the edges of the program's flow graph. The collecting semantics of the program is the least fixed point of these equations in which the set on the edge entering the start state contains all possible initial environments. Similarly, type inferencing establishes a set of recursive equations between the type stores on the edges of the flow graph. The least fixed point of these type inferencing equations is computable using iterative methods. This is discussed in Chapter 19. The fact that these equations have solutions is due to the fact that the equations in the collecting semantics have a solution and the fact that each abstraction maintains the “structure” of the problem, simply discarding some details.

Chapter 19 also extends type inferencing to handle the entire Icon language. Chapter 22 uses the information from type inferencing to optimize the generated code.

## Chapter 16

# Liveness Analysis of Intermediate Values

The maintenance of intermediate values during expression evaluation in the Icon programming language is more complicated than it is for conventional languages such as C and Pascal. O’Bagy explains this in her dissertation [tr88-31.]:

“Generators prolong the lifetime of temporary values. For example, in

`i = find(s1,s2)`

the operands of the comparison operation cannot be discarded when `find` produces its result. If `find` is resumed, the comparison is performed again with subsequent results from `find(s1,s2)`, and the left operand must still be available.”

In some implementation models, it is equally important that the operands of `find` still be available if that function is resumed (this depends on whether the operand locations are used during resumption or whether all needed values are saved in the local state of the function).

As noted in Chapter 14, a stack-based model handles the lifetime problem dynamically. However, a temporary-variable model like the one used in this compiler requires knowledge at compile-time of the lifetime of intermediate values. In a straightforward implementation of conventional languages, liveness analysis of intermediate values is trivial: an intermediate value is computed in one place in the generated code, is used in one place, and is live in the contiguous region between the computation and the use. In such languages, determining the lifetime of intermediate values only becomes complicated when certain optimizations are performed, such as code motion and common subexpression elimination across basic blocks [dragonbk,progflw.]. This is not true in Icon. In the presence of goal-directed evaluation, the lifetime of an intermediate value can extend beyond the point of use. Even in a straightforward implementation, liveness analysis is not trivial.

In its most general form, needed in the presence of the optimizations mentioned above, liveness analysis requires iterative methods. However, goal-directed evaluation imposes enough structure on the liveness problem that, at least in the absence of optimizations, iterative methods are not needed to solve it. This chapter presents a simple and accurate method for computing liveness information for intermediate values in Icon. The analysis is formalized in an attribute grammar.

## 16.1 Implicit Loops

Goal-directed evaluation extends the lifetime of intermediate values by creating implicit loops within an expression. In O'Bagy's example, the start of the loop is the generator `find` and the end of the loop is the comparison that may fail. An intermediate value may be used within such a loop, but if its value is computed before the loop is entered, it is not recomputed on each iteration and the temporary variable must not be reused until the loop is exited.

The following fragment of C code contains a loop and is therefore analogous to code generated for goal-directed evaluation. It is used to demonstrate the liveness information needed by a temporary variable allocator. In the example, `v1` through `v4` represent intermediate values that must be assigned to program variables.

```
v1 = f1();
while (--v1) {
    v2 = f2();
    v3 = v1 + v2;
    f3(v3);
}
v4 = 8;
```

Separate variables must be allocated for `v1` and `v2` because they are both needed for the addition. Here, `x` is chosen for `v1` and `y` is chosen for `v2`.

```
x = f1();
while (--x) {
    y = f2();
    v3 = x + y;
    f3(v3);
}
v4 = 8;
```

`x` cannot be used to hold `v3`, because `x` is needed in subsequent iterations of the loop. Its lifetime must extend through the end of the loop. `y`, on the other hand, can be used because it is recomputed in subsequent iterations. Either variable may be used to hold `v4`.

```
x = f1();
while (--x) {
    y = f2();
```

```

    y = x + y;
    f3(y);
  }
x = 8;

```

Before temporary variables can be allocated, the extent of the loops created by goal-directed evaluation must be estimated. Suppose O'Bagy's example

```
i = find(s1, s2)
```

appears in the following context

```

procedure p(s1, s2, i)
  if i = find(s1, s2) then return i + *s1
  fail
end

```

The simplest and most pessimistic analysis assumes that a loop can appear anywhere within the procedure, requiring the conclusion that an intermediate value in the expression may live to the end of the procedure. Christopher's simple analysis [tccompile.] notices that the expression appears within the control clause of an if expression. This is a bounded context; implicit loops cannot extend beyond the end of the control clause. His allocation scheme reuses, in subsequent expressions, temporary variables used in this control clause. However, it does not determine when temporary variables can be reused within the control clause itself.

The analysis presented here locates the operations within the expression that can fail and those that can generate results. It uses this information to accurately determine the loops within the expression and the intermediate values whose lifetimes are extended by those loops.

## 16.2 Liveness Analysis

It is instructive to look at a specific example where intermediate values must be retained beyond (in a lexical sense) the point of their use. The following expression employs goal-directed evaluation to conditionally write sentences in the data structure *x* to an output file. Suppose *f* is either a file or null. If *f* is a file, the sentences are written to it; if *f* is null, the sentences are not written.

```
every write(\f, !x, ".")
```

In order to avoid the complications of control structures at this point in the discussion, the following equivalent expression is used in the analysis:

```
write(\f, !x, ".") & &fail
```

Figure 16.1: The lifetime of temporary variables (with backtracking)

this expression can be converted into a sequence of primitive operations producing intermediate values ( $v1$ ,  $v2$ , ...). This is shown in figure 16.1. For convenience, the operations are expressed in Icon, except that the assignments do not dereference their right-hand operands.

Whether or not the program variables and constants are actually placed in temporary variables depends on the machine model, implementation conventions, and what optimizations are performed. Clearly a temporary variable is not needed for `&fail`. However, temporary variables are needed if the subexpressions are more complex; intermediate values are shown for all subexpressions for explanatory purposes.

When `&fail` is executed, the `!` operation is resumed. This creates an implicit loop from the `!` to `&fail`, as shown by the arrow in the above diagram. The question is: What intermediate values must be retained up to `&fail`? A more instructive way to phrase the question is: After `&fail` is executed, what intermediate values could be reused without being recomputed? From the sequence of primitive operations, it is clear that the reused values include  $v1$  and  $v3$ , and, if the element generation operator, `!`, references its argument after resumption, then the reused values include  $v4$ .  $v2$  is not used within the loop,  $v5$  and  $v6$  are recomputed within the loop, and  $v7$  and  $v8$  are not used. The lines in the diagram to the left of the code indicate the lifetime of the intermediate values. The dotted portion of each line represents the region of the lifetime beyond what would exist in the absence of backtracking.

Liveness information could be computed by making the implicit loops explicit then performing a standard liveness analysis in the form of a global data flow analysis. That is unnecessarily expensive. There is enough structure in this particular liveness problem that it can be solved during the simple analysis required to locate the implicit loops caused by goal-directed evaluation.

Several concepts are needed to describe analyses involving execution order within Icon expressions. *Forward execution order* is the order in which operations would be executed at run time in the absence of goal-directed evaluation and explicit loops. Goal-directed evaluation involves both failure and the resumption of suspended generators. The control clause of an if-then-else expression

may fail, but instead of resuming a suspending generator, it causes the `else` clause to be executed. This failure results in forward execution order. Forward execution order imposes a partial ordering on operations. It produces no ordering between the `then` and the `else` clauses of an `if` expression. *Backtracking order* is the reverse of forward execution order. This is due to the LIFO resumption of suspended generators. The backward flow of control caused by looping control structures does not contribute to this liveness analysis (intermediate results used within a looping control structure are also computed within the loop), but is dealt with in later chapters. The every control structure is generally viewed as a looping control structure. However, it simply introduces failure. Looping only occurs when it is used with a generative control clause, in which case the looping is treated the same as goal-directed evaluation.

A notation that emphasizes intermediate values, subexpressions, and execution order is helpful for understanding how liveness is computed. Both postfix notation and syntax trees are inadequate. A postfix notation is good for showing execution order, but tends to obscure subexpressions. The syntax tree of an expression shows subexpressions, but execution order must be expressed in terms of a tree walk. In both representations, intermediate values are implicit. For this discussion, an intermediate representation is used. A subexpression is represented as a list of explicit intermediate values followed by the operation that uses them, all enclosed in ovals. Below each intermediate value is the subexpression that computes it. This representation is referred to as a *postfix tree*. The postfix tree for the example above is:

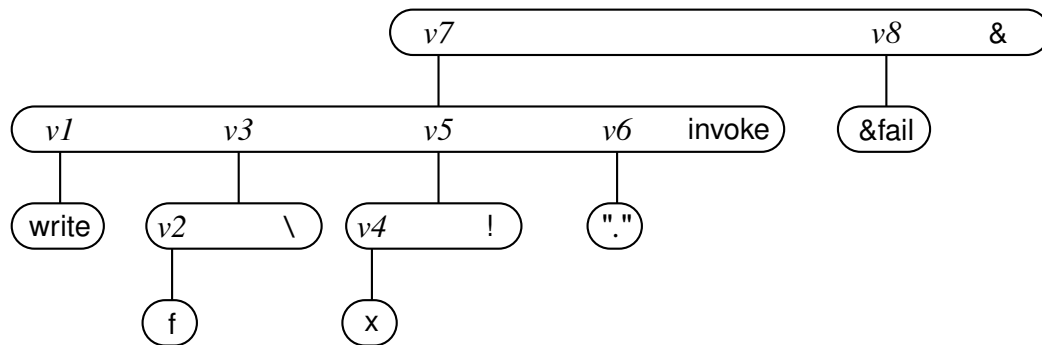

Figure 16.2: A postfix tree for `write(\f, !x, ".") & &fail`

In this notation, the forward execution order of operations (which includes constants and references to program variables) is left-to-right and the backtracking order is right-to-left. In this example, the backtracking order is `&fail`, `invoke`, `."`, `!`, `x`, `\`, `f`, and `write`.

As explained above, the use of an intermediate value must appear in an implicit loop for the value to have an extended lifetime. Two events are needed to create such a loop. First, an operation must fail, initiating backtracking. Second, an operation must be resumed, causing execution to proceed forward again. This analysis computes the maximum lifetime of intermediate values in the expression, so it only needs to compute the rightmost operation (within a bounded expression) that

can fail. This represents the end of the farthest reaching loop. Once execution proceeds beyond this point, no intermediate value can be reused.

The intermediate values of a subexpression are used at the end of the subexpression. For example, `invoke` uses the intermediate values `v1`, `v3`, `v5`, and `v6`; the following figure shows these intermediate results and the operation in isolation.

Figure 16.3: The temporary values used by `invoke`

In order for these uses to be in a loop, backtracking must be initiated from outside; that is, beyond the subexpression (in the example, only `&fail` and `&` are beyond the subexpression).

In addition, for an intermediate value to have an extended lifetime, the beginning of the loop must start after the intermediate value is computed. Two conditions may create the beginning of a loop. First, the operation itself may be resumed. In this case, execution continues forward within the operation. It may reuse any of its operands and none of them are recomputed. The operation does not have to actually generate more results. For example, reversible swap (the operator `<->`) can be resumed to reuse both of its operands, but it does not generate another result. Whether an operation actually reuses its operands on resumption depends on its implementation. In the Icon compiler, operations implemented with a C function using the standard calling conventions always use copies of operands on resumption, but implementations tailored to a particular use often reference operand locations on resumption. Liveness analysis is presented here as if all operations reuse their operands on resumption. In the actual implementation, liveness analysis computes a separate lifetime for values used internally by operations and the code generator decides whether this lifetime applies to operands. This internal lifetime may also be used when allocating tended descriptors for variables declared local to the in-line code for an operation. The behavior of the temporary-variable model presented in this dissertation can be compared with one developed by Nilsen and Martinek [Martinek]; it also relies on the liveness analysis described in this chapter.

The second way to create the beginning of a loop is for a subexpression to generate results. Execution continues forward again and any intermediate values to the left of the generative subexpression may be reused without being recomputed. Remember, backtracking is initiated from outside the expression. Suppose an expression that can fail is associated with `v6`, in the previous figure. This creates a loop with the generator associated with `v5`. However, this particular loop does not include `invoke` and does not contribute to the reuse of `v1` or `v3`.

A resumable operation and generative subexpressions are all *resumption points* within an expression. A simple rule can be used to determine which intermediate values of an expression have extended lifetimes: If the expression can be resumed, the intermediate values with extended lifetimes consist of those to the left of the rightmost resumption point of the expression. This rule refers to the “top level” intermediate values. The rule must be applied recursively to subexpressions to

determine the lifetime of lower level intermediate values.

It sometimes may be necessary to make conservative estimates of what can fail and of resumption points (for liveness analysis, it is conservative to overestimate what can fail or be resumed). For example, invocation may or may not be resumable, depending on what is being invoked and, in general, it cannot be known until run time what is being invoked (for the purposes of this example analysis, it is assumed that the variable *write* is not changed anywhere in the program).

In the example, the rightmost operation that can fail is *&fail*. Resumption points are *!* and the subexpressions corresponding to the intermediate values *v5* and *v7*.

Once the resumption points have been identified, the rule for determining extended lifetimes can be applied. If there are no resumption points in an expression, no intermediate values in that expression can be reused. Applying this rule to the postfix tree above yields *v1*, *v3*, and *v4* as the intermediate values that have extended lifetimes.

Similar techniques can be used for liveness analysis of Prolog programs, where goal-directed evaluation also creates implicit loops. One difference is that a Prolog clause is a linear sequence of calls. It does not need to be “linearized” by constructing a postfix tree. Another difference is that all intermediate values in Prolog programs are stored in explicit variables. A Prolog variable has a lifetime that extends to the right of its last use if an implicit loops starts after the variable’s first use and ends after the variable’s last use.

## 16.3 An Attribute Grammar

To cast this approach as an attribute grammar, an expression should be thought of in terms of an abstract syntax tree. The transformation from a postfix tree to a syntax tree is trivial. It is accomplished by deleting the explicit intermediate values. A syntax tree for the example is:

Figure 16.4: A syntax tree for `write(\f, !x, ".") & fail`

Several interpretations can be given to a node in a syntax tree. A node can be viewed as representing either an operation, an entire subexpression, or an intermediate value.

This analysis associates four attributes with each node (this ignores attributes needed to handle break expressions). The goal of the analysis is to produce the lifetime attribute. The other three attributes are used to propagate information needed to compute the lifetime.

- **resumer** is either the rightmost operation (represented as a node) that can initiate backtracking into the subexpression or it is null if the subexpression cannot be resumed.
- **failer** is related to **resumer**. It is the rightmost operation that can initiate backtracking that can continue past the subexpression. It is the same as **resumer**, unless the subexpression itself contains the rightmost operation that can fail.

item **gen** is a boolean attribute. It is true if the subexpression can generate multiple results if resumed.

- **lifetime** is the operation beyond which the intermediate value is no longer needed. It is either the parent node, the **resumer** of the parent node, or null. The lifetime is the parent node if the value is never reused after execution leaves the parent operation. The lifetime is the **resumer** of the parent if the parent operation or a generative sibling to the right can be resumed. A lifetime of null is used to indicate that the intermediate value is never used. For example, the value of the control clause of an if expression is never used.

Attribute computations are associated with productions in the grammar. The attribute computations for **failer** and **gen** are always for the non-terminal on the left-hand side of the production. These values are then used at the parent production; they are effectively passed up the syntax tree. The computations for **resumer** and **lifetime** are always for the attributes of non-terminals on the right-hand side of the production. **resumer** is then used at the productions defining these non-terminals; it is effectively passed down the syntax tree. **lifetime** is usually saved just for the code generator, but it is sometimes used by child nodes.

## 16.4 Primary Expressions

Variables, literals, and keywords are primary expressions. They have no subexpressions, so their productions contain no computations for **resumer** or **lifetime**. The attribute computations for a literal follow. A literal itself cannot fail, so backtracking only passes beyond it if the backtracking was initiated before (to the right of) it. A literal cannot generate multiple results.

```

expr ::= literal {
    expr.failer := expr.resumer
    expr.gen := false
}
```

Another example of a primary expression is the keyword `&fail`. Execution cannot continue past `&fail`, so it must be the rightmost operation within its bounded expression that can fail. A pre-existing attribute, `node`, is assumed to exist for every symbol in the grammar. It is the node in the syntax tree that corresponds to the symbol.

```

expr ::= &fail {
    expr.failer := expr.node
    expr.gen := false
}

```

## 16.5 Operations with Subexpressions

Addition provides an example of the attribute computations involving subexpressions. The following diagram shows how `resumer`, `failer`, and `gen` information would be passed through the postfix tree.

Figure 16.5: Passing attribute information through a postfix tree

This information would then be used to compute lifetime information for `v1` and `v2`. Figure 16.6 shows how the attribute information is actually passed through the syntax tree.

The lifetime attributes are computed for the roots of the subtrees for `expr1` and `expr2`.

The details of the attribute computations depend, in part, on the characteristics of the individual operation. Addition does not fail, so the rightmost resumer, if there is one, of `expr2` is the rightmost resumer of the entire expression. The rightmost resumer of `expr1` is the rightmost operation that can initiate backtracking that continues past `expr2`. Addition does not suspend, so the lifetime of the value produced by `expr2` only extends through the operation (that is, it always is recomputed in the presence of goal-directed evaluation). If `expr2` is a generator, then the result of `expr1` must

Figure 16.6: Passing attribute information through a syntax tree

be retained for as long as  $\text{expr}_2$  might be resumed. Otherwise, it need only be retained until the addition is performed.  $\text{expr}_1$  is the first thing executed in the expression, so its *failer* is the *failer* for the entire expression. The expression is a generator if either  $\text{expr}_1$  or  $\text{expr}_2$  is a generator (note that the operation  $|$  is logical *or*, not Icon's alternation control structure):

```

expr ::= expr1 + expr2 {
    expr2.resumer := expr.resumer
    expr2.lifetime := expr.node
    expr1.resumer := expr2.failer
    if expr2.gen & (expr.resumer ≠ null) then
        expr1.lifetime := expr.resumer
    else
        expr1.lifetime := expr.node
    expr.failer := expr1.failer
    expr.gen := (expr1.gen | expr2.gen)
}

```

*/expr* provides an example of an operation that can fail. If there is no rightmost resumer of the entire expression, it is the rightmost resumer of the operand. The lifetime of the operand is simply the operation, by the same argument used for  $\text{expr}_2$  of addition. The computation of *failer* is also analogous to that of addition. The expression is a generator if the operand is a generator:

```

expr ::= /expr1 {
    if expr.resumer = null then
        expr1.resumer := expr.node
    else
        expr1.resumer := expr.resumer
}

```

```

    expr1.lifetime := expr.node
    expr.failer := expr1.failer
    expr.gen := expr1.gen
  }

```

`!expr` differs from `/expr` in that it can generate multiple results. If it can be resumed, the result of the operand must be retained through the rightmost resumer:

```

expr ::= !expr1 {
  if expr.resumer = null then {
    expr1.resumer := expr.node
    expr1.lifetime := expr.node
  }
  else {
    expr1.resumer := expr.resumer
    expr1.lifetime := expr.resumer
  }
  expr.failer := expr1.failer
  expr.gen := true
}

```

## 16.6 Control Structures

Other operations follow the general pattern of the ones presented above. Control structures, on the other hand, require unique attribute computations. In particular, several control structures bound subexpressions, limiting backtracking. For example, `not` bounds its argument and discards the value. If it has no resumer, then it is the rightmost operation that can fail. The expression is not a generator:

```

expr ::= not expr1 {
  expr1.resumer := null
  expr1.lifetime := null
  if expr.resumer = null then
    expr.failer := expr.node
  else
    expr.failer := expr.resumer
  expr.gen := false
}

```

}

$\text{expr}_1 ; \text{expr}_2$  bounds  $\text{expr}_1$  and discards the result. Because the result of  $\text{expr}_2$  is the result of the entire expression, the code generator makes their result locations synonymous. This is reflected in the lifetime computations. Indeed, all the attributes of  $\text{expr}_2$  and those of the expression as a whole are the same:

```

expr ::= expr1 ; expr2 {
    expr1.resumer := null
    expr1.lifetime := null
    expr2.resumer := expr.resumer
    expr2.lifetime := expr.lifetime
    expr.failer := expr2.failer
    expr.gen := expr2.gen
}

```

A reasonable implementation of alternation places the result of each subexpression into the same location: the location associated with the expression as a whole. This is reflected in the lifetime computations. The resumer of the entire expression is also the resumer of each subexpression. Backtracking out of the entire expression occurs when backtracking out of  $\text{expr}_2$  occurs. This expression is a generator:

```

expr ::= expr1 | expr2 {
    expr2.resumer := expr.resumer
    expr2.lifetime := expr.lifetime
    expr1.resumer := expr.resumer
    expr1.lifetime := expr.lifetime
    expr.failer := expr2.failer
    expr.gen := true
}

```

The first operand of an if expression is bounded and its result is discarded. The other two operands are treated similar to those of alternation. Because there are two independent execution paths, the rightmost resumer may not be well-defined. However, it is always conservative to treat the resumer as if it is farther right than it really is; this just means that an intermediate value is kept around longer than needed. If there is no resumer beyond the if expression, but at least one of the branches can fail, the failure is treated as if it came from the end of the if expression (represented by the node for the expression). Because backtracking out of an if expression is rare, this inaccuracy is of little practical consequence. The if expression is a generator if either branch is a generator:

```

expr ::= if expr1 then expr2 else expr3 {
    expr3.resumer := expr.resumer
    expr3.lifetime := expr.lifetime
    expr2.resumer := expr.resumer
    expr2.lifetime := expr.lifetime
    expr1.resumer := null
    expr1.lifetime := null
    if expr.resumer = null & (expr1.failer ≠ null | expr2.failer ≠ null) then
        expr.failer := expr.node
    else
        expr.failer = expr.resumer
    expr.gen := (expr2.gen | expr3.gen)
}

```

The do clause of every is bounded and its result discarded. The control clause is always resumed at the end of the loop and can never be resumed by anything else. The value of the control clause is discarded. Ignoring break expressions, the loop always fails:

```

expr ::= every expr1 do expr2 {
    expr2.resumer := null
    expr2.lifetime := null
    expr1.resumer := expr.node
    expr1.lifetime := null
    expr.failer := expr.node
    expr.gen := false
}

```

Handling break expressions requires some stack-like attributes. These are similar to the ones used in the control flow analyses described in O'Bagy's dissertation [.tr88-31.] and the ones used to construct flow graphs in the original technical report on type inferencing.

The attributes presented here can be computed with one walk of the syntax tree. At a node, subtrees are processed in reverse execution order: first the resumer and lifetime attributes of a subtree are computed, then the subtree is walked. Next the failer and gen attributes for the node itself are computed, and the walk moves back up to the parent node.

# Chapter 17

## Overview of the Compiler

### 17.1 Components of the Compiler

The Icon compiler is divided into two components: a run-time system and the compiler itself. This organization is illustrated below. In the diagram, labeled boxes represent programs, other text (some of it delimited by braces) represents files, and arrows represent data flow.

Figure 17.1: Organization of the compiler and run-time system

The run-time system appears above the dotted line and the compiler itself appears below the line. The programs shown with the run-time system are executed once when the run-time system

is installed or updated. They build a data base, `rt.db`, and an object-code library, `rt.a`, for use by the compiler. The general definition of the term “data base” is used here: a collection of related data. `rt.db` is stored as a text file. It is accessed and manipulated in internal tables by the programs `rtt` and `iconc`. The `rtt` program is specific to the Icon compiler system and is described below. The C compiler and the library maintenance program are those native to the system on which the Icon compiler is being used. The format of the object-code library is dictated by the linker used with the C compiler. The file `rt.h` contains C definitions shared by the routines in the run-time system and code generated by the compiler.

The diagram of the compiler itself reflects the fact that the Icon compiler uses a C compiler and linker as a back end. However, `iconc` automatically invokes these programs, so the Icon programmer sees a single tool that takes Icon source as input and produces an executable file.

## 17.2 The Run-time System

As with the run-time system for the interpreter, the run-time system for the compiler implements Icon’s operations. However, the compiler has needs beyond those of the interpreter. In the interpreter’s run-time system, all operations are implemented as C functions conforming to certain conventions. The interpreter uses the same implementation of an operation for all uses of the operation. While this approach results in acceptable performance for many Icon programs, the purpose of an optimizing compiler is to obtain better performance. A major goal in the development of `iconc` is to use information from type inferencing to tailor the parameter passing and parameter type conversions of an operation to particular uses of the operation and to place code in line where appropriate. The compiler needs a mechanism to support this tailored operation invocation. In addition, the compiler needs information about the properties of operations for use in performing type inferencing and other analyses.

In addition to supporting the analyses and optimizations of `iconc`, there are several other major goals in the design of the compiler’s run-time system. These include

- Specification of all information about an operation in one place.
- Use of one coding to produce both general and tailored implementation of an operation.
- Use of the pre-existing run-time system as a basis for the new one.

Most of the design goals for the run-time system would best be served by a special-purpose language in which to implement the run-time system. Such a language would allow the properties of an operation needed by various analyses to be either explicitly coded or easily inferred from parts of the code used to produce an implementation of the operation. The language would also allow easy recognition and manipulation of parts of the code that need to be tailored to individual

uses of an operation. In addition, the language would provide support for features of Icon such as its data types and goal-directed evaluation.

While a special-purpose language is consistent with most design goals, it is not consistent with using the interpreter's run-time system written in C as a basis for that of the compiler. A special-purpose language also has the problem that it requires a large effort to implement. These conflicting goals are resolved with a language that is a compromise between an ideal special-purpose implementation language and C. The core of the language is C, but the language contains special features for specifying those aspects of a run-time operation that must be dealt with by the compiler. This language is called the *implementation language* for the Icon compiler's run-time system. Because the implementation language is designed around C, much of the detailed code for implementing an operation can be borrowed from the interpreter system with only minor changes. The important facets of the implementation language are discussed here. A full description of the language can be found in the reference manual for the language [ipd79.]. The core material from this reference manual is included as Appendix A of this dissertation.

### 17.3 The Implementation Language

The implementation language is used to describe the operators, keywords, and built-in functions of Icon. In addition to these operations, the run-time system contains routines to support other features of Icon such as general invocation, co-expression activation, and storage management. These other routines are written in C.

The program `rtt` takes as input files containing operations coded in the implementation language and translates the operations into pure C. `rtt` also builds the data base, `rt.db`, with information about the operations. In addition to operations written in the implementation language, `rtt` input may contain C functions. These C functions can use several of the extensions available to the detailed C code in the operations. These extensions are translated into ordinary C code. While not critical to the goals of the run-time system design, the ability to use these extensions in otherwise ordinary C functions is very convenient.

The definition of an operation is composed of three layers. The outer layer brackets the code for the operation. It consists of a header at the beginning of the code and the reserved word `end` at the end of the code. The header may be preceded by an optional description of the operation in the form of a string literal; this description is used only for documentation. The second layer consists of type checking and type conversion code. Type checking code may be nested. The inner layer is the detailed C code, abstract type computations, and code to handle run-time errors. An abstract type computation describes the possible side-effects and result types of the operation in a form that type inferencing can use. This feature is needed because it is sometimes impractically difficult to deduce this information from the C code. The code to handle run-time errors is exposed; that is, it is not buried within the detailed C code. Because of this, type inferencing can easily determine conditions

under which an operation terminates without either producing a value or failing. (A further reason for exposing this code is explained in the implementation language reference manual in the section on scoping.)

An operation header starts with one of the three reserved words `operator`, `function`, or `keyword`. The header contains a description of the operation's *result sequence*, that is, how many results it can produce. This includes both the minimum and maximum number of results, with `*` indicating an unbounded number. In addition, it indicates, by a trailing `+`, when an operation can be resumed to perform a side-effect after it has produced its last result. This information is somewhat more detailed than can easily be inferred by looking at the `returns`, `suspends`, and `fails` in the detailed C code. The information is put in the data base for use by the analysis phases of `iconc`.

An operation header also includes an identifier. This provides the name for built-in functions and keywords. For all types of operations, `rtt` uses the identifier to construct the names of the C functions that implement the operations. The headers for operators also include an operator symbol. The parser for `iconc` is not required to use this symbol for the syntax of the operation, but for most operations it does so; list creation, `[...]`, is an example of an exception. The headers for built-in functions and operators include a parameter list. The list provides names for the parameters and indicates whether dereferenced and/or undereferenced versions of the corresponding argument are needed by the operation. It also indicates whether the operation takes a variable number of arguments.

The following are five examples of operation headers.

```
function{0,1+} move(i)
```

```
function{} bal(c1,c2,c3,s,i,j)
```

```
operator{1} [...] llist(elems[n])
```

```
operator{0,1} / null(underef x -> dx)
```

```
keyword{3} regions
```

`move` is a function that takes one argument. It may produce zero or one result and may be resumed to produce a side effect after its last result. `bal` is a function that takes six arguments. It produces an arbitrary number of results. The list-creation operator is given the symbol `[...]` (which may be used for string invocation, if string invocation is enabled) and is given the name `llist`. It takes an arbitrary number of arguments with `elems` being the array of arguments and `n` being the number of arguments. List creation always produces one result. The `/` operator is given the name `null`. It takes one argument, but both undereferenced and dereferenced versions are needed by the operation. It produces either zero or one result. `&regions` is a keyword that produces three results.

Type checking and type conversion constructs consist of an if-then construct, an if-then-else construct, a `type_case` construct that selects code to execute based on the type of an argument, and a `len_case` construct that selects code to execute based on the number of arguments in the variable part of a variable-length argument list. The conditions in the if-then and if-then-else constructs are composed of operations that check the types of arguments or attempt to convert arguments to specific types.

A type check starts with “is:”. This is followed by the name of a type and an argument in parentheses. For example, the then clause of the following if is executed if `x` is a list.

```
if is:list(x) then ...
```

A type conversion is similar to a type check, but starts with “cnv:”. For example, the following code attempts to convert `s` to a string. If the conversion succeeds, the then clause of the if is executed.

```
if cnv:string(s) then ...
```

There are forms of conversion that convert a null value into a specified default value, forms that put a converted value in a location other than the parameter, and forms that convert Icon values into certain types of C values. The later type of conversion is convenient because the detailed code is expressed in C. In addition, exposing conversions back and forth between Icon and C values leaves open the possibility of future optimizations to eliminate unnecessary conversions to Icon values. The control clause of an if may also use limited forms of expressions involving boolean operators. The full syntax and semantics of conversions are described in the implementation language reference manual.

Detailed code is expressed in a slightly extended version of C and is introduced by one of two constructs. The first is

```
inline { extended C }
```

This indicates that it is reasonable for the Icon compiler to put the detailed code in line. The second construct is

```
body { extended C }
```

This indicates that the detailed code is too large to be put in line and should only appear as part of a C function in the run-time library. The person who codes the operation is free to decide which pieces of detailed code are suitable to in-lining and which are not. The decision is easily changed, so an operation can be fine tuned after viewing the code produced by the compiler.

One extension to C is the ability to declare variables that are tended with respect to garbage collection. Another extension is the ability to use some constructs of the implementation language, such as type conversions, within the C code. An important extension is the inclusion of `return`, `suspend`, and `fail` statements that are analogous to their Icon counterparts. This extension, combined with the operation headers, makes the coding of run-time routines independent of the C calling

conventions used in the compiler system. The return and suspend statements have forms that convert C values to Icon values, providing inverses to conversions in the type checking code of the implementation language.

This mechanism is more than is necessary for those keywords that are simple constants. For keywords that are string, cset, integer, or real constants there is a special form of definition. The Icon compiler treats keywords coded with these definitions as manifest constants. When future versions of the Icon compiler implement constant folding, that optimization will be automatically applied to these keywords.

## 17.4 Standard and Tailored Operation Implementations

For every operation that it translates, except keywords, rtt creates a C function conforming to the standard calling conventions of the compiler system. With the help of the C compiler and library maintenance routine, rtt puts an object module for that function in the compiler system's run-time library. This function is suitable for invocation through a procedure block. It is used with unoptimized invocations.

rtt creates an entry in the data base for every operation it translates, including keywords. This entry contains the code for the operation. The code is stored in the data base in a form that is easier to parse and process than the original source, and the body statements are replaced by calls to C functions. These C functions are in the run-time library and implement the code from the body statement. The calling conventions for these functions are tailored to the needs of the code and do not, in general, conform to the standard calling conventions of the compiler system.

When the compiler can determine that a particular operation is being invoked, it locates the operation in the data base and applies information from type inferencing to simplify or eliminate the code in the operation that performs type checking and conversions on arguments. These simplifications will eliminate detailed code that will never be executed in this invocation of the operation. The compiler can attempt the simplification because the type checking code is in the data base in a form that is easily dealt with. If enough simplification is possible, a tailored version of the operation is generated in line. This tailored version includes the simplified type checking code, if there is any left. For detailed code that has not been eliminated by the simplification, the tailored version also includes the C code from inline statements and includes calls to the functions that implement the code in body statements. The process of producing tailored versions of built-in operations is described in more detail in a later chapter.

Ideally, when unique types can be inferred for the operands of an operation, the compiler should either produce a small piece of type-specific in-line C code or produce a call to a type-specific C function implementing the operation. It is possible to code operations in the implementation language such that the compiler can do this. In addition, this is the natural way to code most operations. For the few exceptions, there are reasonable compromises between ideal generated

code and elegant coding in the implementation language. This demonstrates that the design and implementation of the run-time system and its communication with the compiler is successful.

# Chapter 18

## Organization of Iconc

The Icon compiler, `iconc`, takes as input the source code for an Icon program and, with the help of a C compiler and linker, produces an executable file. The source code may be contained in several files, but `iconc` does not support separate compilation. It processes an entire program at once. This requirement simplifies several of the analyses, while allowing them to compute more accurate information. Without the entire program being available, the effects of procedures in other files is unknown. In fact, it is not possible to distinguish built-in functions from missing procedures. Type inferencing would be particularly weakened. It would have to assume that any call to an undeclared variable could have any side effect on global variables (including procedure variables) and on any data structure reachable through global variables or parameters.

### 18.1 Compiler Phases

Iconc is organized into a number of phases. These are illustrated in the diagram on the following page.

The initialization phase includes reading a data base of information about run-time routines into internal tables. This information is used in many of the other phases.

The source analysis phase consists of a lexical analyzer and parser. These are adapted from those used in the interpreter system. The parser generates abstract syntax trees and symbol tables for all procedures before subsequent phases are invoked. The symbol resolution phase determines the scope of variables that are not declared in the procedures where they are used. This resolution can only be done completely after all source files for the program are read. If a variable does not have a local declaration, the compiler checks to see whether the variable is declared global (possibly as a procedure or record constructor) in one of the source files. If not, the compiler checks to see whether the variable name matches that of a built-in function. If the name is still not resolved, it is considered to be a local variable.

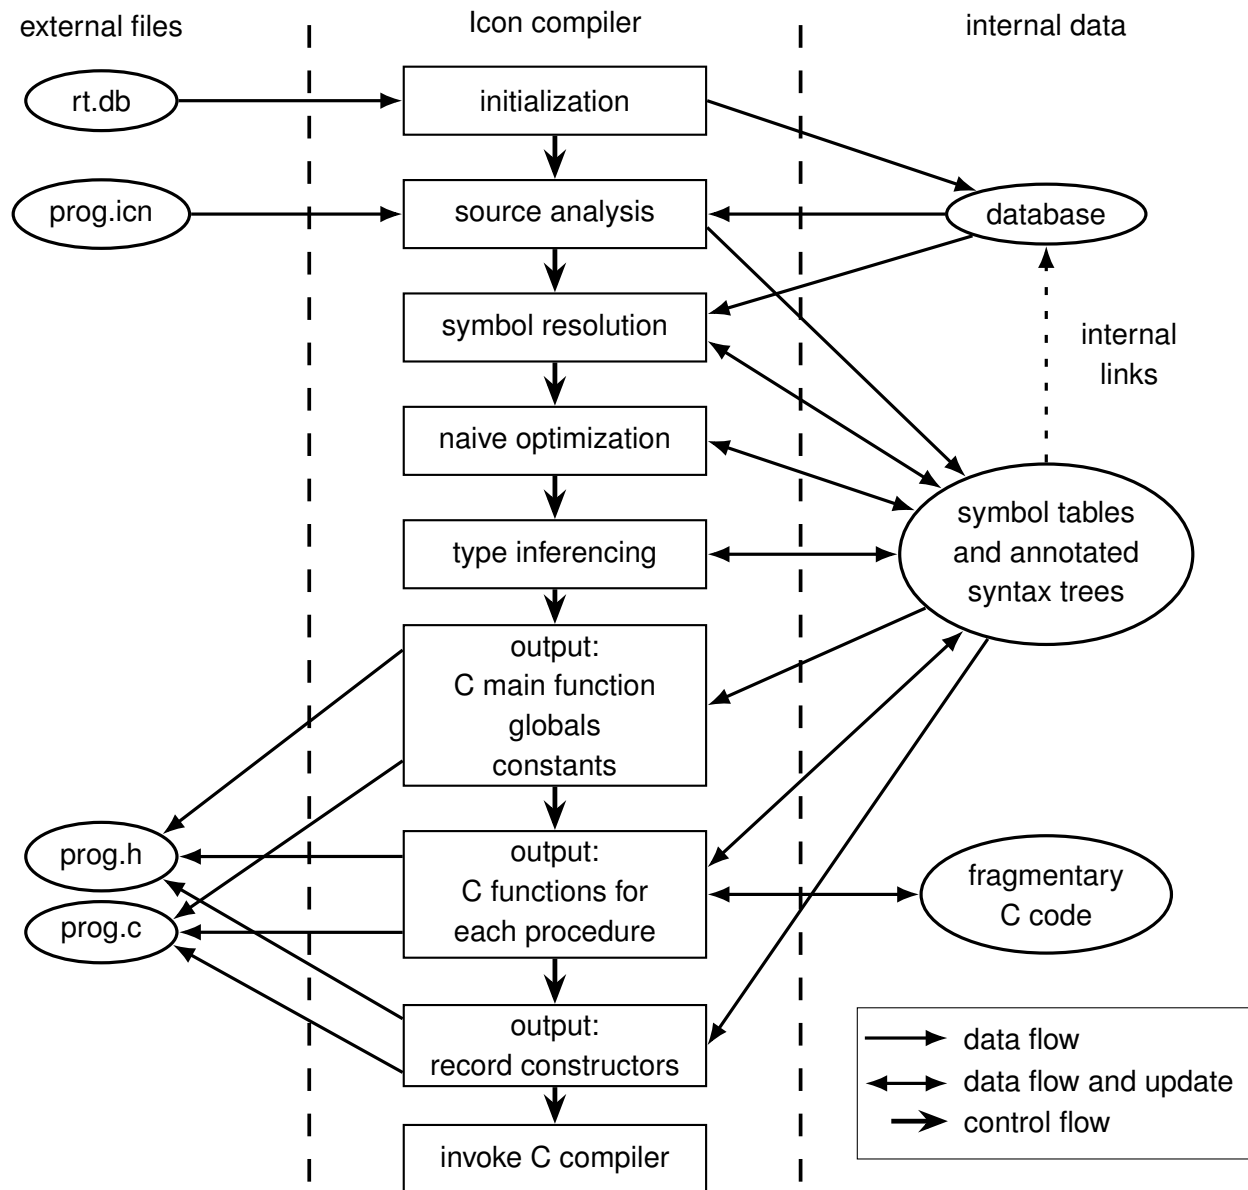

Figure 18.1: Compiler phases and data flow

## 18.2 Naive Optimizations

Naive optimizations involve invocation and assignment. These optimizations are done before type inferencing to aid that analysis. Certain “debugging features” of Icon such as the variable function interfere with these optimizations. By default, these features are disabled. If the user of iconc requests the debugging features, these optimizations are bypassed. While these optimizations are being done, information is gathered about whether procedures suspend, return, or fail. This information is used in several places in the compiler.

The invocation optimization replaces general invocation by a direct form of invocation to a procedure, a built-in function, or a record constructor. This optimization involves modifying nodes in the syntax tree. It only applies to invocations where the expression being invoked is a global variable initialized to a value in one of the three classes of procedure values. First, the Icon program is analyzed to determine which variables of this type appear only as the immediate operands of invocations. No such variable is ever assigned to, so it retains its initial value throughout the program (a more exact analysis could be done to determine the variables that are not assigned to, but this would seldom yield better results in real Icon programs because these programs seldom do anything with procedure values other than invoke them). This means that all invocations of these variables can be replaced by direct invocations. In addition, the variables themselves can be discarded as they are no longer referenced.

The invocation optimization improves the speed of type inferencing in two ways, although it does nothing to improve the accuracy of the information produced. Performing type inferencing on direct invocations is faster than performing it on general invocations. In addition, type inferencing has fewer variables to handle, which also speeds it up.

The invocation optimization does improve code generated by the compiler. In theory, the optimization could be done better after type inferencing using the information from that analysis, but in practice this would seldom produce better results. On most real Icon programs, this optimization using the naive analysis replaces all general invocations with direct ones.

As noted in Chapter 15, it is important for type inferencing to distinguish strong updates from weak updates. The data base contains a general description of assignment, but it would be difficult for a type inferencing system to use the description in recognizing that a simple assignment or an augmented assignment to a named variable is a strong update. It is much easier to change general assignments where the left hand side is a named variable to a special assignment and have type inferencing know that the special assignment is a strong update. Special-casing assignment to named variables is also important for code generation. General optimizations to run-time routines are not adequate to produce the desired code for these assignments. The optimizations to assignment are described in Chapter 22.

The details of type inferencing are described in other chapters. Producing code for the C main function, global variables, constants, and record constructors is straightforward. C code is written to two files for organizational purposes; it allows definitions and code to be written in parallel.

## 18.3 Code Generation for Procedures

Producing code for procedures involves several sub-phases. The sub-phases are liveness analysis, basic code generation, fix-up and peephole optimization, and output. During this phase of code generation, procedures are processed one at a time.

These sub-phases are described in later chapters. The code fix-up phase and peephole optimization are performed during the same pass over the internal representation of the C code. Some clean-up from peephole optimization is performed when the code is written. The logical organization of the compiler places the fix-up phase as a pass in code generation with peephole optimization being a separate phase. The organization of this dissertation reflects the logical organization of the compiler rather than its physical organization.

The physical organization of this phase is shown in the following diagram.

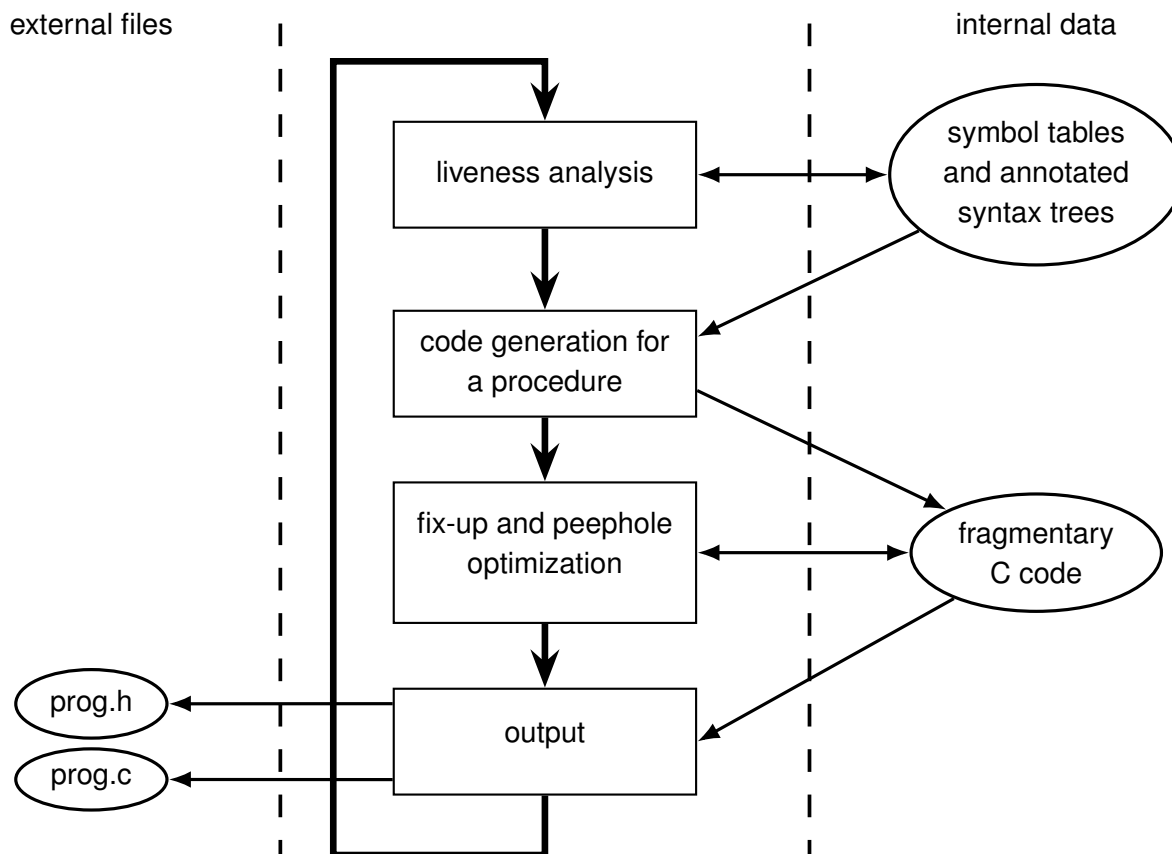

Figure 18.2: The physical organization of the code generation phase

# Chapter 19

## The Implementation of Type Inferencing

Chapter 15 develops a theoretical type inferencing model for Icon, called Model 3. The purpose of that chapter is to explain the relationship between type inferencing and the semantics of Icon; for simplicity, some features of the language along with certain questions of practical importance are ignored in that chapter. This chapter describes the implementation of the type inferencing system used in the Icon compiler. The implementation is based on Model 3. This chapter describes solutions to those issues that must be addressed in developing a complete practical type inferencing system from Model 3. The issues include:

- the representation of types and stores
- the development of a type system for the full Icon language
- the handing of procedure calls and co-expression activation
- the determination of edges in the flow graph
- the computation of a fixed point for type information

In addition, performance of the abstract interpretation must be considered. This includes both speed and memory usage.

### 19.1 The Representation of Types and Stores

A type consists of a set of basic types (technically, it is a union of basic types, but the constituents of the basic types are not explicitly represented). The operations needed for these sets are: add a basic type to a set, form the union of two sets, form the intersection of two sets, test for membership in a set, and generate members of a subrange of basic types (for example, generate all members that are list types). A bit vector is used for the set representation, with a basic type represented by an

integer index into the vector. The required operations are simple and efficient to implement using this representation. Unless the sets are large and sparse, this representation is also space efficient. While the sets of types are often sparse, for typical programs, they are not large.

A store is implemented as an array of pointers to types. A mapping is established from variable references to indexes in the store. In the type inferencing model, Model 3, presented in Chapter 15, there is one kind of store that contains all variables. In the actual implementation, temporary variables need not be kept in this store. The purpose of this store is to propagate a change to a variable to the program points affected by the change. A temporary variable is set in one place in the program and used in one place; there is nothing to determine dynamically. It is both effective and efficient to store the type of a temporary variable in the corresponding node of the syntax tree.

Another level of abstraction can be developed that requires much less memory than Model 3, but it must be modified to produce good results. This abstraction abandons the practice of a store for every edge in the flow graph. Instead it has a single store that is a merger of all the stores in Model 3 (the type associated with a variable in a merged store is the union of the types obtained for that variable from each store being merged). For variables that are truly of one type throughout execution, this abstraction works well. Named variables do not have this property. They have an initial null value and usually are assigned a value of another type during execution. Because assignments to named variables are treated as strong updates, Model 3 can often deduce that a variable does not contain the null type at specific points in the flow graph.

For structure variables this further abstraction does work well in practice. These variables are initialized to the empty type (that is, no instances of these variables exist at the start of program execution), so the problem of the initial null type does not occur. Sometimes instances of these variables are created with the null type and later changed. However, the fact that assignments to these variables must be treated as weak updates means that type inferencing must assume that these variables can always retain their earlier type after an assignment. Propagating type information about structure variables through the syntax tree does not help much in these circumstances. While it is possible to construct example programs where Model 3 works better for structure variables than this further abstraction, experiments with prototype type inferencing systems indicate that the original system seldom gives better information for real programs [tr88-25].

Type inferencing in the compiler is implemented with two kinds of stores: local stores that are associated with edges in the flow graph and contain named variables (both local and global variables) and a global store that contains structure variables (in the implementation, the global store is actually broken up by structure-variable type into several arrays).

## 19.2 A Full Type System

Model 3 from Chapter 15 includes no structure type other than lists, nor does it consider how to handle types for procedure and co-expression values to allow effective type inferencing in their

presence. This section develops a complete and effective type system for Icon.

Most of the structure types of Icon are assigned several subtypes in the type inferencing system. As explained for lists in Chapter 15, these subtypes are associated with the program points where values of the type are created. The exception to this approach is records. One type is created per record declaration. While it is possible to assign a subtype to each use of a record constructor, in practice a given kind of record usually is used consistently with respect to the types of its fields throughout a program. The extra subtypes would require more storage while seldom improving the resulting type information.

For efficiency, the size of the bit vectors representing types and the size of the stores need to remain fixed during abstract interpretation. This means that all subtypes must be determined as part of the initialization of the type inferencing system. In order to avoid excessive storage usage, it is important to avoid creating many subtypes for program points where structures are not created. The invocation optimization described in Chapter 19 helps determine where structures can and cannot be created by determining for most invocations what operation is used. The type inferencing system determines what structures an operation can create by examining the abstract type computations associated with the operation in the data base. A new clause in an abstract type computation indicates that a structure can be created. The following example is the abstract type computation from the built-in function list. It indicates the the function creates and returns a new list with elements whose type is the same as that of the parameter *x* (the second parameter).

```
abstract {
    return new list(type(x))
}
```

This is the clause as written by the programmer developing the run-time library; it is translated into an internal form for storage in the data base.

Invocation optimizations may not identify the operation associated with some invocations. The initialization phase of type inferencing skips these invocations. Type inferencing may later discover that one of these invocations can create a structure. Each structure type is given one subtype that is used for all of these later discoveries. While it is possible for there to be several of these creation points representing logically distinct subtypes, this seldom occurs in practice. If it does happen, type inferencing produces a correct, but less precise, result.

The type system contains representations for all run-time values that must be modeled in the abstract interpretation. These run-time values can be divided into three categories, each of which is a superset of the previous category:

- the first-class Icon values
- the intermediate values of expression evaluation

- the values used internally by Icon operations

Just as these categories appear in different places during the execution of an Icon program, the corresponding types appear in different places during abstract interpretation. If certain types cannot appear as the result of a particular type computation, it is not necessary to have elements in the bit vector produced by the computation to represent those types. It is particularly important to minimize the memory used for stores associated with edges of the flow graph (this is discussed more in the last section of this chapter). These stores contain only the types of the smallest set listed above: the first-class values.

Types (or subtypes) are allocated bit vector indexes. The first-class types may appear as the result of any of the three classes of computation. They are allocated indexes at the front of the bit vectors. If they are the only types that can result from an abstract computation, the bit vector for the result has no elements beyond that of the last first-class types. The first-class types are:

- null
- string
- cset
- integer
- real
- file
- list subtypes
- set subtypes
- table subtypes
- record subtypes
- procedure subtypes
- co-expression subtypes

The list subtypes are allocated with

- one for the argument to the main procedure
- one for each easily recognized creation point
- one representing all other lists

The set subtypes are allocated with

- one for each easily recognized creation point
- one representing all other sets

The table subtypes are allocated with

- one for each easily recognized creation point
- one representing all other tables

The record subtypes are allocated with one for each record declaration. The procedure subtypes are allocated with

- one for each procedure
- one for each record constructor
- one for each built-in function
- one representing operators available for string invocation

Note that procedure subtypes are allocated after most procedure and function values have been eliminated by invocation optimizations (the procedures and functions are still there, they are just not Icon values). Therefore, few of these subtypes are actually allocated. The co-expression subtypes are allocated with

- one for the main co-expression
- one for each create expression

The bit vectors used to hold the intermediate results of performing abstract interpretation on expressions must be able to represent the basic types plus the variable reference types. Variable reference types are allocated bit vector indexes following those of the basic types. The bit vectors for intermediate results are just long enough to contain these two classifications of types. The variable reference types are

- integer keyword variable types
- &pos
- &subject
- substring trapped variable types

- table-element trapped variable types
- list-element reference types
- table assigned-value reference types
- field reference types
- global variable reference types
- local variable reference types

`&random` and `&trace` behave the same way from the perspective of the type inferencing system, so they are grouped under one type as integer keyword variables. The fact that `&pos` can cause assignment to fail is reflected in the type inferencing system, so it is given a separate type. `&subject` is the only string keyword variable so it is in a type by itself.

Substring trapped variables and table-element trapped variables are “hidden” structures in the implementation of Icon. They appear as intermediate results, but are only indirectly observable in the semantics of Icon. In order to reflect these semantics in the type inferencing system, there are substring trapped variable types and table-element trapped variable types. These are structure types similar to sets, but are variable reference types rather than first-class types. The substring trapped variable types are allocated with

- one for each easily recognized creation point
- one representing all other substring trapped variables

The table-element trapped variable types are allocated with

- one for each easily recognized creation point
- one representing all other table-element trapped variables

List elements, table assigned-values, and record fields are all variables that can appear as the intermediate results of expression evaluation. The type system has corresponding variable reference types to represent them. The list-element reference types are allocated with one for each list types. The table assigned-value reference types are allocated with one for each table type. The field reference types are allocated with one for each record field declaration.

Identifiers are variables and are reflected in the type system. The global variable reference types are allocated with

- one for each global variable (except those eliminated by invocation optimizations).

- one for each static variable

The local variable reference types are allocated with one for each local variable, but the bit vector indexes and store indexes are reused between procedures. The next section describes why this reuse is possible.

Icon's operators use a number of internal values that never "escape" as intermediate results. Some of these internal values are reflected in the type system in order to describe the semantics of the operations in the abstract interpretation. The full set of types that can be used to express these semantics are presented in the syntax of the abstract type computations of the run-time implementation language; see Appendix G. In addition to the types of intermediate results, these types include

- set-element reference types
- table key reference types
- table default value reference types
- references to the fields within substring trapped variables that reference variables
- references to fields within table-element trapped variables that reference tables

These types are allocated bit vector indexes at the end of the type system. The only bit vectors large enough to contain them are the temporary bit vectors used during interpretation of the abstract type computations of built-in operations.

Set elements, table keys, and table default values do not appear as variable references in the results of expression evaluation. However, it is necessary to refer to them in order to describe the effects of certain Icon operations. For this reason, they are included in the type system. The set-element reference types are allocated with one for each set type. The table key reference types are allocated with one for each table type. The table default value reference types are allocated with one for each table type.

Substring trapped variable types contain references to the variable types being trapped and table-element trapped variable types contain references to the table types containing the element being trapped. These references are fields within these trapped variable types. There is one field reference type for each trapped variable type.

## 19.3 Procedure Calls and Co-Expression Activations

A type inferencing system for the full Icon language must handle procedures and co-expressions. As noted above, each procedure and each create expression is given its own type. This allows

the type inferencing system to accurately determine which procedures are invoked and what co-expressions might be activated by a particular expression.

The standard semantics for procedures and co-expressions can be implemented using stacks of procedure activation frames, with one stack per co-expression. The first frame, on every stack except that of the main co-expression, is a copy of the frame for the procedure that created the co-expression. The local variables in this frame are used for evaluating the code of the co-expression. The type inferencing system uses a trivial abstraction of these procedure frame stacks, while capturing the possible transfers of control induced by procedure calls and co-expression activations.

The type inferencing system, in effect, uses an environment that has one frame per procedure, where that frame is a summary of all frames for the procedure that could occur in a corresponding environment of an implementation of the standard semantics. The frame is simply a portion of the store that contains local variables. Because no other procedure can alter a local variable, it is unnecessary to pass the types of local variables into procedure calls. If the called procedure returns control via a return, suspend, or fail, the types are unchanged, so they can be passed directly across the call. This allows the type inferencing system to keep only the local variables of a procedure in the stores on the edges of the flow graph for the procedure, rather than keeping the local variables of all procedures. Global variables must be passed into and out of procedure calls. Because static variables may be altered in recursive calls, they must also be passed into and out of procedure calls.

A flow graph for an entire program is constructed from the flow graphs for its individual procedures and co-expressions. An edge is added from every invocation of a procedure to the head of that procedure and edges are added from every return, suspend, and fail back to the invocation. In addition, edges must be added from an invocation of a procedure to all the suspends in the procedure to represent resumption. When it is not possible to predetermine which procedure is being invoked, edges are effectively added from the invocation to all procedures whose invocation cannot be ruled out based on the naive invocation optimizations. Edges are effectively added between all co-expressions and all activations, and between all activations. Information is propagated along an edge when type inferencing deduces that the corresponding procedure call or co-expression activation might actually occur. The representation of edges in the flow graph is discussed below.

Type inferencing must reflect the initializations performed when a procedure is invoked. Local variables are initialized to the null value. On the first call to the procedure, static variables are also initialized to the null value. The initialization code for the standard semantics is similar to

```
initialize locals
if (first_call) {
    initialize statics
    user initialization code
}
```

In type inferencing, the variables are initialized to the null type and the condition on the if is

ignored. Type inferencing simply knows that the first-call code is executed sometimes and not others. Before entering the main procedure, global variables are set to the null type and all static variables are set to the empty type. In some sense, the empty type represents an impossible execution path. Type inferencing sees paths in the flow graph from the start of the program to the body of a procedure that never pass through the initialization code. However, static variables have an empty type along this path and no operation on them is valid. Invalid operations contribute nothing to type information.

## 19.4 The Flow Graph and Type Computations

In order to determine the types of variables at the points where they are used, type inferencing must compute the contents of the stores along edges in the flow graph. Permanently allocating the store on each edge can use a large amount of memory. The usage is

$$M = E(G + S + L)T/8$$

$M$	—	total memory, expressed in bytes, used by stores.
$E$	—	the number of edges in the program flow graph.
$G$	—	the number of global variables in the program.
$S$	—	the number of static variables in the program.
$L$	—	the maximum number of local variables in any procedure.
$T$	—	the number of types in the type system.

Large programs with many structure creation points can produce thousands of edges, dozens of variables, and hundreds of types, requiring megabytes of memory to represent the stores.

The code generation phase of the compiler just needs the (possibly dereferenced) types of operands, not the stores. If dereferenced types are kept at the expressions where they are needed, it is not necessary to keep a store with each edge of the flow graph.

Consider a section of straight-line code with no backtracking. Abstract interpretation can be performed on the graph starting with the initial store at the initial node and proceeding in execution order. At each node, the store on the edge entering the node is used to dereference variables and to compute the next store if there are side effects. Once the computations at a node are done, the store on the edge entering the node is no longer needed. If updates are done carefully, they can be done in-place, so that the same memory can be used for both the store entering a node and the one leaving it.

In the case of branching control paths (as in a case expression), abstract interpretation must proceed along one path at a time. The store at the start the branching of paths must be saved for use with each path. However, it need only be saved until the last path is interpreted. At that point, the memory for the store can be reused. When paths join, the stores along each path must be merged. The merging can be done as each path is completed; the store from the path can then be reused

in interpreting other paths. When all paths have been interpreted, the merged store becomes the current store for the node at the join point.

The start of a loop is a point where control paths join. Unlike abstract interpretation for the joining of simple branching paths, abstract interpretation for the joining of back edges is not just a matter of interpreting all paths leading to the join point before proceeding. The edge leaving the start of the loop is itself on a path leading to the start of the loop. Circular dependencies among stores are handled by repeatedly performing the abstract interpretation until a fixed point is reached. In this type inferencing system, abstract interpretation is performed in iterations, with each node in the flow graph visited once per iteration. The nodes are visited in execution order. For back edges, the store from the previous iteration is used in the interpretation. The stores on these edges must be kept throughout the interpretation. These stores are initialized to map all variables to the empty type. This represents the fact that the abstract interpretation has not yet proven that execution can reach the corresponding edge.

The type inferencing system never explicitly represents the edges of the flow graph in a data structure. Icon is a structured programming language. Many edges are implicit in a tree walk performed in forward execution order – the order in which type inferencing is performed. The location of back edges must be predetermined in order to allocate stores for them, but the edges themselves are effectively recomputed as part of the abstract interpretation.

There are two kinds of back edges. The back edges caused by looping control structures can be trivially deduced from the syntax tree. A store for such an edge is kept in the node for the control structure. Other back edges are induced by goal-directed evaluation. These edges are determined with the same techniques used in liveness analysis. A store for such an edge is kept in the node of the suspending operation that forms the start of the loop. Because the node can be the start of several nested loops, this store is actually the merged store for the stores that theoretically exist on each back edge.

At any point in abstract interpretation, three stores are of interest. The *current store* is the store entering the node on which abstract interpretation is currently being performed. It is created by merging the stores on the incoming edges. The *success store* is the store representing the state of computations when the operation succeeds. It is usually created by modifying the current store. The *failure store* is the store representing the state of computations when the operation fails.

In the presence of a suspended operation, the failure store is the store kept at the node for that operation. A new failure store is established whenever a resumable operation is encountered. This works because abstract interpretation is performed in forward execution order and resumption is LIFO. Control structures, such as if-then-else, with branching and joining paths of execution, cause difficulties because there may be more than one possible suspended operation when execution leaves the control structure. This results in more than one failure store during abstract interpretation. Rather than keeping multiple failure stores when such a control structure has operations that suspend on multiple paths, type inferencing pretends that the control structure ends with an operation that does nothing other than suspend and then fail. It allocates a store for this operation

in the node for the control structure. When later operations that fail are encountered, this store is updated. The failure of this imaginary operation is the only failure seen by paths created by the control structure and the information needed to update the failure stores for these paths is that in the store for this imaginary operation. This works because the imaginary operation just passes along failure without modifying the store.

In the case where a control structure transforms failure into forward execution, as in the first subexpression of a compound expression, the failure store is allocated (with empty types) when the control structure is encountered and deallocated when it is no longer needed. If no failure can occur, no failure store need be allocated. The lack of possible failure is noted while the location of back edges is being computed during the initialization of type inferencing. Because a failure store may be updated at several operations that can fail, these are weak updates. Typically, a failure store is updated by merging the current store into it.

The interprocedural flow graph described earlier in this chapter has edges between invocations and returns, suspends, and fails. Type inferencing does not maintain separate stores for these theoretical edges. Instead it maintains three stores per procedure that are mergers of stores on several edges. One store is the merger of all stores entering the procedure because of invocation; this store contains parameter types in addition to the types of global and static variables. Another store is the merger of all stores entering the procedure because of resumption. The third store is the merger of all stores leaving the procedure because of returns, suspends, and fails. There is also a result type associated with the procedure. It is updated when abstract interpretation encounters returns and suspends.

Two stores are associated with each co-expression. One is the merger of all stores entering the co-expression and the other is the merger of all stores leaving the co-expression. Execution can not only leave through an activation operator, it can also re-enter through the activation. The store entering the activation is a merger of the stores entering all co-expressions in which the activation can occur. Because a procedure containing an activation may be called from several co-expressions, it is necessary to keep track of those co-expressions. A set of co-expressions is associated with each procedure for this purpose. Each co-expression also contains a type for the values transmitted to it. The result type of an activation includes the result types for all co-expressions that might be activated and the types of all values that can be transmitted to a co-expression that the activation might be executed in.

When type inferencing encounters the invocation of a built-in operation, it performs abstract interpretation on the representation of the operation in the data base. It interprets the type-checking code to see what paths might be taken through the operation. The interpretation uses the abstract type computations and ignores the detailed C code when determining the side effects and result type of the operation. Because the code at this level of detail contains no loops, it is not necessary to save stores internal to operations. An operation is re-interpreted at each invocation. This allows type inferencing to produce good results for polymorphous operations. At this level, the code for an operation is simple enough that the cost of re-interpretation is not prohibitive. All side effects

within these operations are treated as weak updates; the only strong updates recognized by type inferencing are the optimized assignments to named variables (see Chapter 18).

The abstract semantics of control structures are hard-coded within the type inferencing system. The system combines all the elements described in this chapter to perform the abstract interpretation. A global flag is set any time an update changes type information that is used in the next iteration of abstract interpretation. The flag is cleared between iterations. If the flag is not set during an iteration, a fixed point has been reached and the interpretation halts.

# Chapter 20

## Code Generation

This chapter describes the code generation process. The examples of generated code presented here are produced by the compiler, but some cosmetic changes have been made to enhance readability.

Code generation is done one procedure at a time. An Icon procedure is, in general, translated into several C functions. There is always an *outer function* for the procedure. This is the function that is seen as implementing the procedure. In addition to the outer function, there may be several functions for success continuations that are used to implement generative expressions.

The outer function of a procedure must have features that support the semantics of an Icon call, just as a function implementing a run-time operation does. In general, a procedure must have a procedure block at run time. This procedure block references the outer function. All functions referenced through a procedure block must conform to the compiler system's standard calling conventions. However, invocation optimizations usually eliminate the need for procedure variables and their associated procedure blocks. When this happens, the calling conventions for the outer function can be tailored to the needs of the procedure.

As explained in Chapter 14, the standard calling convention requires four parameters: the number of arguments, a pointer to the beginning of an array of descriptors holding the arguments, a pointer to a result location, and a success continuation to use for suspension. The function itself is responsible for dereferencing and argument list adjustment. In a tailored calling convention for an outer function of a procedure, any dereferencing and argument list adjustment is done at the call site. This includes creating an Icon list for the end of a variable-sized argument list. The compiler produces code to do this that is optimized to the particular call. An example of an optimization is eliminating dereferencing when type inferencing determines that an argument cannot be a variable reference.

The number of arguments is never needed in these tailored calling conventions because the number is fixed for the procedure. Arguments are still passed via a pointer to an array of descriptors, but if there are no arguments, no pointer is needed. If the procedure returns no value, no result location is needed. If the procedure does not suspend, no success continuation is needed.

In addition to providing a calling interface for the rest of the program, the outer function must

provide local variables for use by the code generated for the procedure. These variables, along with several other items, are located in a procedure frame. An Icon procedure frame is implemented as a C structure embedded within the frame of its outer C function (that is, as a local struct definition). Code within the outer function can access the procedure frame directly. However, continuations must use a pointer to the frame. A global C variable, `pfp`, points to the frame of the currently executing procedure. For efficiency, continuations load this pointer into a local register variable. The frame for a main procedure might have the following declaration.

```
struct PF00_main {
    struct p_frame old_pfp;
    dptr old_argp;
    dptr rslt;
    continuation succ_cont;
    struct {
        struct tend_desc *previous;
        int num;
        struct descrip d[5];
    } tend;
};
```

with the definition

```
struct PF00_main frame;
```

in the procedure's outer function. A procedure frame always contains the following five items: a pointer to the frame of the caller, a pointer to the argument list of the caller, a pointer to the result location of this call, a pointer to the success continuation of this call, and an array of tended descriptors for this procedure. It may also contain C integer variables, C double variables, and string and cset buffers for use in converting values. If debugging is enabled, additional information is stored in the frame. The structure `p_frame` is a generic procedure frame containing a single tended descriptor. It is used to define the pointer `old_pfp` because the caller can be any procedure.

The argument pointer, result location, and success continuation of the call must be available to the success continuations of the procedure. A global C variable, `argp`, points the argument list for the current call. This current argument list pointer could have been put in the procedure frame, but it is desirable to have quick access to it. Quick access to the result location and the success continuation of the call is less important, so they are accessed indirectly through the procedure frame.

The array of descriptors is linked onto the chain used by the garbage collector to locate tended descriptors. These descriptors are used for Icon variables local to the procedure and for temporary variables that hold intermediate results. If the function is responsible for dereferencing and

argument list adjustment (that is, if it does not have a tailored calling convention), the modified argument list is constructed in a section of these descriptors.

The final thing provided by the outer function is a *control environment* in which code generation starts. In particular, it provides the bounding environment for the body of the procedure and the implicit failure at the end of the procedure. The following C function is the tailored outer function for a procedure named *p*. The procedure has arguments and returns a result. However, it does not suspend, so it needs no success continuation.

```
static int P01_p(args, rslt)
dptr args;
dptr rslt;
{
    struct PF01_p frame;
    register int signal;
    int i;
    frame.old_pfp = pfp;
    pfp = (struct p_frame *)&frame;
    frame.old_argp = argp;
    frame.rslt = rslt;
    frame.succ_cont = NULL;

    for (i = 0; i < 3; ++i)
        frame.tend.d[i].dword = D_Null;
    argp = args;
    frame.tend.num = 3;
    frame.tend.previous = tend;
    tend = (struct tend_desc *)&frame.tend;
```

*translation of the body of procedure p*

```
L10: /* bound */
L4: /* proc fail */
    tend = frame.tend.previous;
    pfp = frame.old_pfp;
    argp = frame.old_argp;
    return A_Resume;
L8: /* proc return */
    tend = frame.tend.previous;
    pfp = frame.old_pfp;
```

```

    argp = frame.old_argp;
    return A_Continue;
}

```

The initialization code reflects the fact that this function has three tenced descriptors to use for local variables and intermediate results. L10 is both the bounding label and the failure label for the body of the procedure. Code to handle procedure failure and return (except for setting the result value) is at the end of the outer function. As with bounding labels, the labels for these pieces of code have associated signals. If a procedure fail or return occurs in a success continuation, the continuation returns the corresponding signal which is propagated to the outer function where it is converted into a goto. The code for procedure failure is located after the body of the procedure, automatically implementing the implicit failure at the end of the procedure.

## 20.1 Translating Icon Expressions

Icon's goal-directed evaluation makes the implementation of control flow an important issue during code generation. Code for an expression is generated while walking the expression's syntax tree in forward execution order. During code generation there is always a *current failure action*. This action is either "branch to a label" or "return a signal". When the translation of a procedure starts, the failure action is to branch to the bounding label of the procedure body. The action is changed when generators are encountered or while control structures that use failure are being translated.

The allocation of temporary variables to intermediate results is discussed in more detail later. However, some aspects of it will be addressed before presenting examples of generated code. The result location of a subexpression may be determined when the parent operation is encountered on the way down the syntax tree. This is usually a temporary variable, but does not have to be. If no location has been assigned by the time the code generator needs to use it, a temporary variable is allocated for it. This temporary variable is used in the code for the parent operation.

The code generation process is illustrated below with examples that use a number of control structures and operations. Code generation for other features of the language is similar.

Consider the process of translating the following Icon expression:

```
return if a = (1 | 2) then "yes" else "no"
```

When this expression is encountered, there is some current failure action, perhaps a branch to a bounding label. The return expression produces no value, so whether a result location has been assigned to it is of no consequence. If the argument of a return fails, the procedure fails. To handle this possibility, the current failure action is set to branch to the label for procedure failure before translating the argument (in this example, that action is not used). The code for the argument is then generated with its result location set to the result location of the procedure itself. Finally the result

location is dereferenced and control is transferred to the procedure return label. The dereferencing function, `deref`, takes two arguments: a pointer to a source descriptor and a pointer to a destination descriptor.

```
code for the if expression
deref(rslt, rslt);
goto L7 /* proc return */;
```

The control clause of the if expression must be bounded. The code implementing the then clause must be generated following the bounding label for the control clause. A label must also be set up for the else clause with a branch to this label used as the failure action for the control clause. Note that the result location of each branch is the result location of the if expression which is in turn the result location of the procedure. Because neither branch of the if expression contains operations that suspend, the two control paths can be brought together with a branch to a label.

```
code for control clause
L4: /* bound */
    rslt->vword.sptr = "yes";
    rslt->dword = 3;
    goto L6 /* end if */;
L5: /* else */
    rslt->vword.sptr = "no";
    rslt->dword = 2;
L6: /* end if */
```

Using a branch and a label to bring together the two control paths of the if expression is an optimization. If the then or the else clauses contain operations that suspend, the general continuation model must be used. In this model, the code following the if expression is put in a success continuation, which is then called at the end of both the code for the then clause and the code for the else clause.

Next consider the translation of the control clause. The numeric comparison operator takes two operands. In this translation, the standard calling conventions are used for the library routine implementing the operator. Therefore, the operands must be in an array of descriptors. This array is allocated as a sub-array of the tended descriptors for the procedure. In this example, tended location 0 is occupied by the local variable, `a`. Tended locations 1 and 2 are free to be allocated as the arguments to the comparison operator. The code for the first operand simply builds a variable reference.

```

frame.tend.d[1].dword = D_Var;
frame.tend.d[1].vword.descptr = &frame.tend.d[0] /* a */;

```

However, the second operand is alternation. This is a generator and requires a success continuation. In this example, the continuation is given the name P02\_main (the Icon expression is part of the main procedure). The continuation contains the invocation of the run-time function implementing the comparison operator and the end of the bounded expression for the control clause of the if. The function O0o\_numeq implements the comparison operator. The if expression discards the operator's result. This is accomplished by using the variable trashcan as the result location for the call. The compiler knows that this operation does not suspend, so it passes a null continuation to the function. The end of the bounded expression consists of a transfer of control to the bounding label. This is accomplished by returning a signal. The continuation is

```

static int P02_main()
{
  register struct PF00_main *rpf;
  rpf = (struct PF00_main *)pfp;
  switch (O0o_numeq(2, &(rpf->tend.d[1]), &trashcan, (continuation)NULL))
  {
    case A_Continue:
      break;
    case A_Resume:
      return A_Resume;
  }
  return 4; /* bound */
}

```

Each alternative of the alternation must compute the value of its subexpression and call the success continuation. The failure action for the first alternative is to branch to the second alternative. The failure action of the second alternative is the failure action of the entire alternation expression. In this example, the failure action is to branch to the else label of the if expression. In each alternative, a bounding signal from the continuation must be converted into a branch to the bounding label. Note that this bounding signal indicates that the control expression succeeded.

```

frame.tend.d[2].dword = D_Integer;
frame.tend.d[2].vword.integr = 1;
switch (P02_main()) {
  case A_Resume:

```

```

        goto L2 /* alt */;
    case 4 /* bound */:
        goto L4 /* bound */;
    }
L2: /* alt */
    frame.tend.d[2].dword = D_Integer;
    frame.tend.d[2].vword.integr = 2;
    switch (P02_main()) {
        case A_Resume:
            goto L5 /* else */;
        case 4 /* bound */:
            goto L4 /* bound */;
    }

```

The code for the entire return expression is obtained by putting together all the pieces. The result is the following code (the code for P02\_main is not repeated).

```

    frame.tend.d[1].dword = D_Var;
    frame.tend.d[1].vword.descptr = &frame.tend.d[0] /* a */;
    frame.tend.d[2].dword = D_Integer;
    frame.tend.d[2].vword.integr = 1;
    switch (P02_main()) {
        case A_Resume:
            goto L2 /* alt */;
        case 4 /* bound */:
            goto L4 /* bound */;
    }
L2: /* alt */
    frame.tend.d[2].dword = D_Integer;
    frame.tend.d[2].vword.integr = 2;
    switch (P02_main()) {
        case A_Resume:
            goto L5 /* else */;
        case 4 /* bound */:
            goto L4 /* bound */;
    }
L4: /* bound */
    rslt->vword.sptr = yes;

```

```

    rslt->dword = 3;
    goto L6 /* end if */;
L5: /* else */
    rslt->vword.sptr = no;
    rslt->dword = 2;
L6: /* end if */
    deref(rslt, rslt);
    goto L7 /* proc return */;

```

## 20.2 Signal Handling

In order to produce signal handling code, the code generator must know what signals may be returned from a call. These signals may be either directly produced by the operation (or procedure) being called or they may originate from a success continuation. Note that either the operation or the continuation may be missing from a call, but not both. The signals produced directly by an operation are `A_Resume`, `A_Continue`, and `A_FallThru` (this last signal is only used internally within in-line code).

The signals produced by a success continuation belong to one of three categories: `A_Resume`, signals corresponding to labels within the procedure the continuation belongs to, and signals corresponding to labels in procedures farther down in the call chain. The last category only occurs when the procedure suspends. The success continuation for the procedure call may return a signal belonging to the calling procedure. This is demonstrated in the following example (the generated code has been “cleaned-up” a little to make it easier to follow). The Icon program being translated is

```

procedure main()
    write(p())
end
procedure p()
    suspend 1 to 10
end

```

The generative procedure `p` is called in a bounded context. The code generated for the call is

```

switch (P01_p(&frame.tend.d[0], P05_main)) {
    case 7 /* bound */:
        goto L7 /* bound */;

```

```

        case A_Resume:
            goto L7 /* bound */;
    }
    L7: /* bound */

```

This call uses the following success continuation. The continuation writes the result of the call to `p` then signals the end of the bounded expression.

```

static int P05_main() {
    register struct PF00_main *rpfp;

    rpfp = (struct PF00_main *)pfp;
    F0c_write(1, &rpfp->tend.d[0], &trashcan, (continuation)NULL);
    return 7; /* bound */
}

```

The `to` operator in procedure `p` needs a success continuation that implements procedure suspension. Suspension is implemented by switching to the old procedure frame pointer and old argument pointer, then calling the success continuation for the call to `p`. The success continuation is accessed with the expression `rpfp->succ_cont`. In this example, the continuation will only be the function `P05_main`. The suspend must check the signal returned by the procedure call's success continuation. However, the code generator does not try to determine exactly what signals might be returned by a continuation belonging to another procedure. Such a continuation may return an `A_Resume` signal or a signal belonging to some procedure farther down in the call chain. In this example, bounding signal 7 will be returned and it belongs to `main`.

If the call's success continuation returns `A_Resume`, the procedure frame pointer and argument pointer must be restored, and the current failure action must be executed. In this case, that action is to return an `A_Resume` signal to the `to` operator. If the call's success continuation returns any other signal, that signal must be propagated back through the procedure call. The following function is the success continuation for the `to` operator.

```

static int P03_p()
{
    register int signal;
    register struct PF01_p *rpfp;

    rpfp = (struct PF01_p *)pfp;
    deref(rpfp->rslt, rpfp->rslt);
}

```

```

    pfp = rpfp->old_pfp;
    argp = rpfp->old_argp;

    signal = (*rpfp->succ_cont)();
    if (signal != A_Resume) {
        return signal;
    }
    pfp = (struct p_frame *)rpfp;
    argp = NULL;
    return A_Resume;
}

```

The following code implements the call to the to operator. The signal handling code associated with the call must pass along any signal from the procedure call's success continuation. These signals are recognized by the fact that the procedure frame for the calling procedure is still in effect. At this point, the signal is propagated out of the procedure p. Because the procedure frame is about to be removed from the C stack, the descriptors it contains must be removed from the tended list.

```

frame.tend.d[0].dword = D_Integer;
frame.tend.d[0].vword.integr = 1;
frame.tend.d[1].dword = D_Integer;
frame.tend.d[1].vword.integr = 10;
signal = OOk_to(2, &frame.tend.d[0], rslt, P03_p);
if (pfp != (struct p_frame *)&frame) {
    tend = frame.tend.previous;
    return signal;
}
switch (signal) {
    case A_Resume:
        goto L2 /* bound */;
}
L2: /* bound */

```

So far, this discussion has not addressed the question of how the code generator determines what signals might be returned from a call. Because code is generated in execution order, a call involving a success continuation is generated before the code in the continuation is generated. This makes it difficult to know what signals might originate from the success continuation. This

problem exists for direct calls to a success continuation and for calls to an operation that uses a success continuation.

The problem is solved by doing code generation in two parts. The first part produces incomplete signal handling code. At this time, code to handle the signals produced directly by an operation is generated. The second part of code generation is a fix-up pass that completes the signal handling code by determining what signals might be produced by success continuations.

The code generator constructs a call graph of the continuations for a procedure. Some of these calls are indirect calls to a continuation through an operation. However, the only effect of an operation on signals returned by a continuation is to intercept `A_Resume` signals. All other signals are just passed along. This is true even if the operation is a procedure. This call graph of continuations does not contain the procedure call graph nor does it contain continuations from other procedures.

Forward execution order imposes a partial order on continuations. A continuation only calls continuations strictly greater in forward execution order than itself. Therefore the continuation call graph is a DAG.

The fix-up pass is done with a bottom-up walk of the continuation call DAG. This pass determines what signals are returned by each continuation in the DAG. While processing a continuation, the fix-up pass examines each continuation call in that continuation. At the point it processes a call, it has determined what signals might be returned by the called continuation. It uses this information to complete the signal handling code associated with the call and to determine what signals might be passed along to continuations higher up the DAG. If a continuation contains code for a suspend, the fix-up pass notes that the continuation may return a *foreign* signal belonging to another procedure call. As explained above, foreign signals are handled by special code that checks the procedure frame pointer.

## 20.3 Temporary Variable Allocation

The code generator uses the liveness information for an intermediate value when allocating a temporary variable to hold the value. As explained in Chapter 16, this information consists of the furthest program point, represented as a node in the syntax tree, through which the intermediate value must be retained. When a temporary variable is allocated to a value, that variable is placed on a *deallocation list* associated with the node beyond which its value is not needed. When the code generator passes a node, all the temporary variables on the node's deallocation list are deallocated.

The code generator maintains a *status array* for temporary variables while it is processing a procedure. The array contains one element per temporary variable. This array is expandable, allowing a procedure to use an arbitrary number of temporary variables. In a simple allocation scheme, the status of a temporary variable is either *free* or *in-use*. The entry for a temporary variable is initially marked free, it is marked in-use when the variable is allocated, and it is marked free again when the variable is deallocated.

The simple scheme works well when temporary variables are allocated independently. It does not work well when arrays of contiguous temporary variables are allocated. This occurs when temporary variables are allocated to the arguments of a procedure invocation or any invocation conforming to the standard calling conventions; under these circumstances, the argument list is implemented as an array. All of the contiguous temporary variables must be reserved before the first one is used, even though many operations may be performed before the last one is needed. Rather than mark a temporary variable in-use before it actually is, the compiler uses the program point where the temporary variable will be used to mark the temporary variable's entry in the status array as *reserved*. A contiguous array of temporary variables are marked reserved at the same time, with each having a different reservation point. A reserved temporary variable may be allocated to other intermediate values as long as it will be deallocated before the reservation point. In this scheme, an entry in a deallocation list must include the previous status of the temporary variable as it might be a reserved status.

The compiler allocates a contiguous subarray of temporary variables for the arguments of an invocation when it encounters the invocation on the way down the syntax tree during its tree walk. It uses a first-fit algorithm to find a large enough subarray that does not have a conflicting allocation. Consider the problem of allocating temporary variables to the expression

$f1(f2(f3(x, f4())), y)$

where  $f1$  can fail and  $f4$  is a generator. The syntax tree for this expression is shown below. Note that invocation nodes show the operation as part of the node label and not as the first operand to general invocation. This reflects the direct invocation optimization that is usually performed on invocations. Each node in the graph is given a numeric label. These labels increase in value in forward execution order.

The following figure shows the operations in forward execution order with lines on the left side of the diagram showing the lifetime of intermediate values. This represents the output of

the liveness analysis phase of the compiler. Because  $f_4$  can be resumed by  $f_1$ , the value of the expression  $x$  has a lifetime that extends to the invocation of  $f_1$ . The extended portion of the lifetime is indicated with a dotted line.

The following series of diagrams illustrate the process of allocating intermediate values. Each diagram includes an annotated syntax tree and a status array for temporary variables. An arrow in the tree shows the current location of the tree walk. A deallocation list is located near the upper right of each node. An element in the list consists of a temporary variable number and the status with which to restore the variable's entry in the status array. If a temporary variable has been allocated to an intermediate value, the variable's number appears near the lower right of the corresponding node.

The status array is shown with four elements. The elements are initialized to  $F$  which indicates that the temporary variables are free. A reserved temporary variable is indicated by placing the node number of the reservation point in the corresponding element. When a temporary variable is actually in use, the corresponding element is set to  $I$ .

Temporary variables are reserved while walking down the syntax tree. The tree illustrated below on the left shows the state of allocation after temporary variables have been allocated for the operands of  $f_1$ . Two contiguous variables are needed. All variables are free, so the first-fit algorithm allocates variables 0 and 1. The status array is updated to indicate that these variables are reserved for nodes 4 and 5 respectively, and the nodes are annotated with these variable numbers. The lifetime information in the previous figure indicates that these variables should be deallocated after  $f_1$  is executed, so the deallocation array for node 6 is updated.

The next step is the allocation of a temporary variable to the operand of  $f_2$ . The intermediate value has a lifetime extending from node 3 to node 4. This conflicts with the allocation of variable 0, but not the allocation of variable 1. Therefore, variable 1 is allocated to node 3 and the deallocation list for node 4 is updated. This is illustrated in the tree on the right:

4	5	F	F
0	1	2	3

4	3	F	F
0	1	2	3

The final allocation requires a contiguous pair of variables for nodes 1 and 2. The value from node 1 has a lifetime that extends to node 6, and the value from node 2 has a lifetime that extends to node 3. The current allocations for variables 0 and 1 conflict with the lifetime of the intermediate value of node 1, so the variables 2 and 3 are used in this allocation. This is illustrated in the tree:

The remaining actions of the allocator in this example mark temporary variables in-use when the code generator uses them and restore previous allocated statuses when temporary variables are deallocated. This is done in the six steps illustrated in the following diagram. The annotations on the graph do not change. Only the node of interest is shown for each step. These steps are performed in node-number order.

In general, the tree walk will alternate up and down the syntax tree. For example, if node 5 had children, the allocation status after the deallocation associated with node 4,

is used to allocate temporary variables to those children. If this requires more than four temporary variables, the status array is extended with elements initialized to  $F$ .

This allocation algorithm is not guaranteed to produce an allocation that uses a minimal number of temporary variables. Indeed, a smaller allocation for the previous example is illustrated in the tree:

While the non-optimality of this algorithm is unlikely to have a measurable effect on the performance of any practical program, the problem of finding an efficient optimal solution is of theoretical interest. Classical results in the area of register allocation do not apply. It is possible to allocate a minimum number of registers from expression trees for conventional languages in polynomial time [dragon.]. The algorithm to do this depends on the fact that registers (temporary variables) are dead as soon as the value they contain is used. This is not true for Icon temporary variables.

The result of Prabhala and Sethi stating that register allocation is NP-complete even in the presence of an infinite supply of registers also does not apply [prabhala subexp.]. Their complexity result derives from performing register allocation in the presence of common subexpression elimination (that is, from performing register allocation on expression DAGS rather than trees) on a 2-address-instruction machine with optimality measured as the minimum number of instructions needed to implement the program. Goal-directed evaluation imposes more structure on lifetimes than common subexpression elimination, the machine model used here is the C language, and optimality is being measure as the minimum number of temporary variables needed.

The Icon temporary variable allocation problem is different from the Prolog variable allocation problem. Prolog uses explicit variables whose lifetimes can have arbitrary overlaps even in the absence of goal-directed evaluation. The Prolog allocation problem is equivalent to the classical graph coloring problem which is NP-complete [debray apr91, dragon.].

If the allocation of a subarray of temporary variables is delayed until the first one is actually needed in the generated code, an optimum allocation results for the preceding example. It is not obvious whether this is true for the general case of expression trees employing goal-directed evaluation. This problem is left for future work.

In addition to holding intermediate values, temporary variables are used as local tended variables within in-line code. This affects the pattern of allocations, but not the underlying allocation technique.

# Chapter 21

## Control Flow Optimizations

### 21.1 Naive Code Generation

Naive code generation does not consider the effects and needs of the immediately surrounding program. The result is often a poor use of the target language. Even sophisticated code generation schemes that consider the effects of relatively large pieces of the program still produce poor code at the boundaries between the pieces. This problem is typically solved by adding a *peephole optimizer* to the compiler to improve the generated code [.peep1,Wulf,Tanenbaum peephole,dragon.]. A peephole optimizer looks at several instructions that are adjacent (in terms of execution) and tries to replace the instructions by better, usually fewer, instructions. It typically analyzes a variety of properties of the instructions such as addressing modes and control flow.

The Icon compiler has a peephole optimizer that works on the internal form of the generated C code and deals only with control flow. The previous examples of generated code contain a number of instances of code where control flow can be handled much better. For example, it is possible to entirely eliminate the following code fragment generated for the example explaining procedure suspension.

```
switch (signal) {
    case A_Resume:
        goto L2 /* bound */;
}
L2: /* bound */
```

This code is produced because the code generator does not take into account the fact that the bounding label happens to immediately follow the test.

## 21.2 Success Continuations

For the C code in the preceding example, it is quite possible that a C compiler would produce machine code that its own peephole optimizer could eliminate. However, it is unlikely that a C compiler would optimize naively generated success continuations. An earlier example of code generation produced the continuation:

```
static int P02_main()
{
    register struct PF00_main *rpfp;

    rpfp = (struct PF00_main *)pfp;
    switch (O0o_numeq(2, &(rpfp->tend.d[1]), &trashcan, (continuation)NULL)) {
        case A_Continue:
            break;
        case A_Resume:
            return A_Resume;
    }
    return 4; /* bound */
}
```

If the statement

```
return 4; /* bound */
```

is brought into the switch statement, replacing the break, then P02\_main consists of a simple operation call (a C call with associated associated signal handling code). This operation call is

```
switch (O0o_numeq(2, &(rpfp->tend.d[1]), &trashcan, (continuation)NULL)) {
    case A_Continue:
        return 4; /* bound */
    case A_Resume:
        return A_Resume;
}
```

P02\_main is called directly in two places in the following code.

```

frame.tend.d[2].dword = D_Integer;
frame.tend.d[2].vword.integr = 1;
switch (P02_main()) {
    case A_Resume:
        goto L2 /* alt */;
    case 4 /* bound */:
        goto L4 /* bound */;
}
L2: /* alt */
frame.tend.d[2].dword = D_Integer;
frame.tend.d[2].vword.integr = 2;
switch (P02_main()) {
    case A_Resume:
        goto L5 /* else */;
    case 4 /* bound */:
        goto L4 /* bound */;
}
L4: /* bound */

```

A direct call to a trivial function can reasonably be replaced by the body of that function. When this is done for a continuation, it is necessary to *compose* the signal handling code of the body of a continuation with that of the call. This is accomplished by replacing each return statement in the body with the action in the call corresponding to the signal returned. The following table illustrates the signal handling composition for the first call in the code. The resulting code checks the signal from O0o\_numeq and performs the final action.

signal from O0o_numeq	signal from P02_main	final action
A_Continue	4	goto L4;
A_Resume	A_Resume	goto L2;

The result of in-lining P02\_main is

```

frame.tend.d[2].dword = D_Integer;
frame.tend.d[2].vword.integr = 1;
switch (O0o_numeq(2, &frame.tend.d[1], &trashcan, (continuation)NULL)) {
    case A_Continue:
        goto L4 /* bound */;
    case A_Resume:

```

```

        goto L2 /* alt */;
    }
L2: /* alt */
    frame.tend.d[2].dword = D_Integer;
    frame.tend.d[2].vword.integr = 2;
    switch (O0o_numeq(2, &frame.tend.d[1], &trashcan,(continuation)NULL)) {
        case A_Continue:
            goto L4 /* bound */;
        case A_Resume:
            goto L5 /* else */;
    }
L4: /* bound */

```

With a little more manipulation, the switch statements can be converted into if statements and the label L2 can be eliminated:

```

frame.tend.d[2].dword = D_Integer;
frame.tend.d[2].vword.integr = 1;
if (O0o_numeq(2, &frame.tend.d[1], &trashcan,(continuation)NULL) == A_Continue)
    goto L4 /* bound */;
frame.tend.d[2].dword = D_Integer;
frame.tend.d[2].vword.integr = 2;
if (O0o_numeq(2, &frame.tend.d[1], &trashcan,(continuation)NULL) == A_Resume)
    goto L5 /* else */;
L4: /* bound */

```

The Icon compiler's peephole optimizer recognizes two kinds of trivial continuations. The kind illustrated in the previous example consists of a single call with associated signal handling. The other kind simply consists of a single return-signal statement. As in the above example, continuations do not usually meet this definition of triviality until control flow optimizations are performed on them. For this reason, the Icon compiler's peephole optimizer must perform some optimizations that could otherwise be left to the C compiler.

## 21.3 Iconc's Peephole Optimizer

The peephole optimizer performs the following optimizations:

- elimination of unreachable code

- elimination of gotos immediately preceding their destinations
- collapse of branch chains
- deletion of unused labels
- collapse of trivial call chains (that is, in-lining trivial continuations)
- deletion of unused continuations
- simplification of signal checking

Unreachable code follows a `goto` or a `return`, and it continues to the first referenced label or to the end of the function. This optimization may eliminate code that returns signals, thereby reducing the number of signals that must be handled by a continuation call. This provides another reason for performing this traditional optimization in the Icon compiler rather than letting the C compiler do it. This code is eliminated when the fix-up pass for signal handling is being performed. `gotos` immediately preceding their labels also are eliminated at this time.

Unused labels usually are eliminated when the code is written out, but they may be deleted as part of a segment of unreachable code. Unused continuations are simply not written out.

A branch chain is formed when the destination of a `goto` is another `goto` or a `return`. A break in a `switch` statement is treated as a `goto`. There may be several `gotos` in a chain. Each `goto` is replaced by the `goto` or `return` at the end of the chain. This may leave some labels unreferenced and may leave some of the intermediate `gotos` unreachable. Branch chains are collapsed during the fix-up pass.

Inter-function optimization is not traditionally considered a peephole optimization. This is because human beings seldom write trivial functions and most code generators do not produce continuations. The Icon compiler, however, uses calls to success continuations as freely as it uses `gotos`. Therefore collapsing trivial call chains is as important as collapsing branch chains.

There are two kinds of calls to trivial continuations: direct calls and indirect calls through an operation. A direct call always can be replaced by the body of the continuation using signal handling code that is a composition of that in the continuation and that of the call. If the continuation consists of just a `return` statement, this means that the call is replaced by the action associated with the returned signal: either another `return` statement or a `goto` statement. For continuations consisting of a call, the composition is more complicated, as demonstrated by the example given earlier in this chapter.

In the case of an indirect call through an operation, the continuation cannot be placed in line. However, there is an optimization that can be applied. Under some circumstances, the compiler produces a continuation that simply calls another continuation. For example, this occurs when compiling the Icon expression

```
every write(!x | end)
```

The compiler allocates a continuation for the alternation, then compiles the expression !x. The element generation operator suspends, so the compiler allocates a continuation for it and code generation proceeds in this continuation. However, the end of the first alternative has been reached so the only code for this continuation is a call to the continuation for the alternation. The continuation for the alternation contains the code for the invocation of write and for the end of the every control structure. The code for the first alternative is

```

frame.tend.d[2].dword = D_Var;
frame.tend.d[2].vword.descptr = &frame.tend.d[0] /* x */;

switch (O0e_bang(1, &frame.tend.d[2], &frame.tend.d[1], P02_main)) {
    case A_Resume:
        goto L1 /* alt */;
}
L1: /* alt */

```

The code for the two continuations are

```

static int P02_main()
{
    switch (P03_main()) {
        case A_Resume:
            return A_Resume;
    }
}

static int P03_main()
{
    register struct PF00_main *rpf;

    rpf = (struct PF00_main *)pfp;
    F0c_write(1, &rpf->tend.d[1], &trashcan, (continuation)NULL);
    return A_Resume;
}

```

The call to `O0e_bang` can be optimized by passing the continuation `P03_main` in place of `P02_main`.

The optimizations that collapse trivial call chains are performed during the fix-up pass for signal handling.

The final peephole optimization involves simplifying the signal handling code associated with a call. In general, signals are handled with a `switch` statement containing a `case` clause for each signal. The C compiler does not know that these signals are the only values that are ever tested by the `switch` statement, nor is the C compiler likely to notice that some cases simply pass along to the next function down in the call chain the signal that was received. The Icon compiler can use this information to optimize the signal handling beyond the level to which the C compiler is able to optimize it. The optimizer may replace the general form of the `switch` statement with a `switch` statement utilizing a `default` clause or with an `if` statement. In some cases, the optimizer completely eliminates signal checking. This optimization is done when the code is written.

# Chapter 22

## Optimizing Invocations

Several optimizations apply to the invocation of procedures and built-in operations. These include optimizations resulting from the application of information from type inferencing, optimizations resulting from the application of lifetime information to passing parameters and returning results, and optimizations involving the generation of in-line code. There are interactions between the optimizations in these three categories.

A primary motivation in developing the Icon compiler was to explore the optimizations that are possible using information from type inferencing. These optimizations involve eliminating type checking and type conversions where type inferencing indicates that they are not needed. Dereferencing is not normally viewed as a type conversion, because variable references are not first-class values in Icon. However, variable references occur as intermediate values and do appear in the type system used by the Icon compiler. Therefore, from the perspective of the compiler, dereferencing is a type conversion.

When a procedure or built-in operation is implemented as a C function conforming to the standard calling conventions of the compiler system, that function is responsible for performing any type checking and type conversions needed by the procedure or operation. For this reason, the checking and conversions can only be eliminated from tailored implementations.

### 22.1 Invocation of Procedures

As explained earlier, a procedure has one implementation: either a standard implementation or a tailored implementation. If the compiler decides to produce a tailored implementation, the caller of the procedure is responsible for dereferencing. When type inferencing determines that an operand is not a variable reference, no dereferencing code is generated. Suppose *p* is a procedure that takes one argument and always fails. If *P01\_p* is the tailored C function implementing *p*, then it takes one argument: a pointer to a descriptor containing the dereferenced Icon argument. Without using type information, the call *p*(3) translates into

```

frame.tend.d[0].dword = D_Integer;
frame.tend.d[0].vword.integr = 3;
deref(&frame.tend.d[0], &frame.tend.d[0]);
P01_p(&frame.tend.d[0]);

```

With the use of type information, the call to deref is eliminated:

```

frame.tend.d[0].dword = D_Integer;
frame.tend.d[0].vword.integr = 3;
P01_p(&frame.tend.d[0]);

```

## 22.2 Invocation and In-lining of Built-in Operations

Icon's built-in operations present more opportunities for these optimizations than procedures, because they can contain type checking and conversions beyond dereferencing. Built-in operations are treated differently than procedures. Except for keywords, there is always a C function in the run-time library that implements the operation using the standard calling conventions. In addition, the compiler can create several tailored in-line versions of an operation from the information in the data base.

It is important to keep in mind that there are two levels of in-lining. An in-line version of an operation always involves the type checking and conversions of the operation (although they may be optimized away during the tailoring process). However, detailed code is placed in-line only if it is specified with an inline statement in the run-time system. If the detailed code is specified with a body statement, the "in-line" code is a function call to a routine in the run-time library. The difference can be seen by comparing the code produced by compiling the expression `~x` to that produced by compiling the expression `/x`. The definition in the run-time implementation language of `cset` complement is

```

operator{1} ~ compl(x)
  if !cnv:tmp_cset(x) then
    runerr(104, x)
  abstract { return cset }
  body {
    ...
  }
end

```

The conversion to `tmp_cset` is a conversion to a `cset` that does not use space in the block region. Instead the `cset` is constructed in a temporary local buffer. The data base entry for the operation indicates that the argument must be dereferenced. The entry has a C translation of the type conversion code with a call to the support routine, `cnv_tcset`, to do the actual conversion. `cnv_tcset` takes three arguments: a buffer, a source descriptor, and a destination descriptor. The entry in the data base has a call to the function `O160_compl` in place of the body statement. This function takes as arguments the argument and the result location of the operation. The code generator ignores the abstract clause. The in-line code for `~x` is

```

    frame.tend.d[3].dword = D_Var;
    frame.tend.d[3].vword.descptr = &frame.tend.d[0] /* x */;
    deref(&frame.tend.d[3], &frame.tend.d[3]);
    if (cnv_tcset(&(frame.cbuf[0]), &(frame.tend.d[3]), &(frame.tend.d[3])))
        goto L1 /* then: compl */;
    err_msg(104, &(frame.tend.d[3]));
L1: /* then: compl */
    O160_compl(&(frame.tend.d[3]) , &frame.tend.d[2]);

```

The following is the definition of the “/” operator. Note that both undereferenced and dereferenced versions of the argument are used.

```

operator{0,1} / null(underef x -> dx)
  abstract {
    return type(x)
  }
  if is:null(dx) then
    inline {
      return x;
    }
  else inline {
    fail;
  }
end

```

In this operation, all detailed code is specified with inline statements. The generated code for `/x` follows. Note that the order of the then and else clauses is reversed to simplify the test. `L3` is the failure label of the expression. The return is implemented as an assignment to the result location, `frame.tend.d[2]`, with execution falling off the end of the in-line code.

```

    frame.tend.d[3].dword = D_Var;
    frame.tend.d[3].vword.descptr = &frame.tend.d[0] /* x */;
    deref(&frame.tend.d[3], &frame.tend.d[4]);
    if (frame.tend.d[4].dword == D_Null)
        goto L2 /* then: null */;
    goto L3 /* bound */;
L2: /* then: null */
    frame.tend.d[2] = frame.tend.d[3];

```

If type inferencing determines a unique type for  $x$  in each of these expressions, the type checking is eliminated from the code. Suppose type inferencing determines that  $x$  can only be of type `cset` in the expression

```
a := ~x
```

If parameter passing and assignment optimizations (these are explained below) are combined with the elimination of type checking, the resulting code is

```
O160_compl(&(frame.tend.d[0] /* x */), &frame.tend.d[1] /* a */);
```

The form of this translated code meets the goals of the compiler design for the invocation of a complicated operation: a simple call to a type-specific C function with minimum parameter passing. The implementation language for run-time operations requires that type conversions be specified in the control clause of an if statement. However, some conversions, such as converting a string to a `cset`, are guaranteed to succeed. If the code generator recognizes one of these conversions, it eliminates the if statement. The only code generated is the conversion and the code to be executed when the conversion succeeds. Suppose type inferencing determines that  $x$  in the preceding example can only be a string. Then the generated code for the example is

```

frame.tend.d[2] = frame.tend.d[0] /* x */;
cnv_tcset(&(frame.cbuf[0]), &(frame.tend.d[2]), &(frame.tend.d[2]));
O160_compl(&(frame.tend.d[2]), &frame.tend.d[1] / a /);

```

## 22.3 Heuristic for Deciding to In-line

The in-line code for the operators shown so far in the section is relatively small. However, the untailored in-line code for operations like the element generation operator, `!`, is large. If tailoring the code does not produce a large reduction in size, it is better to generate a call to the C function in the run-time library that uses the standard calling conventions. A heuristic is needed for deciding when to use in-line code and when to call the standard C function.

A simple heuristic is to use in-line code only when all type checking and conversions can be eliminated. However, this precludes the generation of in-lining code in some important situations. The operator / is used to direct control flow. It should always be used with an operand whose type can vary at run time, and the generated code should always be in-lined. Consider the Icon expression

```
if /x then x := ""
```

The compiler applies parameter-passing optimizations to the sub-expression /x. It also eliminates the return value of the operator, because the value is discarded. An implementation convention for operations allows the compiler to discard the expression that computes the return value. The convention requires that a return expression of an operation not contain user-visible side effects (storage allocation is an exception to the rule; it is visible, but the language makes no guarantees as to when it will occur). The code for /x is reduced to a simple type check. The code generated for the if expression is

```
    if ((frame.tend.d[0] /* x */).dword == D_Null)
        goto L2 /* bound */;
    goto L3 /* bound */;
L2: /* bound */
    frame.tend.d[0] /* x */.vword.sptr = ;
    frame.tend.d[0] /* x */.dword = 0;
L3: /* bound */
```

To accommodate expressions like those in the preceding example, the heuristic used in the compiler is to produce tailored in-line code when that code contains no more than one type check. Only conversions retaining their if statements are counted as a type checks. This simple heuristic produces reasonable code. Future work includes examining more sophisticated heuristics.

## 22.4 In-lining Success Continuations

Suspension in in-line code provides further opportunity for optimization. In general, suspension is implemented as a call to a success continuation. However, if there is only one call to the continuation, it is better not to put the code in a continuation. The code should be generated at the site of the suspension. Consider the expression

```
every p(1 to 10)
```

The implementation of the to operator is

```

operator{*} ... to(from, to)
/*
 * arguments must be integers.
 */
if !cnv:C_integer(from) then
    runerr(101, from)
if !cnv:C_integer(to) then
    runerr(101, to)
abstract {
    return integer
}
inline {
    for ( ; from <= to; ++from) {
        suspend C_integer from;
    }
    fail;
}
end

```

The arguments are known to be integers, so the tailored version consists of just the code in the inline statement. The for statement is converted to gotos and conditional gotos, so the control flow optimizer can handle it (this conversion is done by rtt before putting the code in the data base). The suspend is translated into code to set the result value and a failure label used for the code of the rest of the bounded expression. This code is generated before the label and consists of a call to the procedure p and the failure introduced by the every expression. The generated code follows. The failure for the every expression is translated into goto L4, where L4 is the failure label introduced by the suspend. The control flow optimizer removes both the goto and the label. They are retained here to elucidate the code generation process.

```

frame.tend.d[1].dword = D_Integer;
frame.tend.d[1].vword.integr = 1;
frame.tend.d[2].dword = D_Integer;
frame.tend.d[2].vword.integr = 10;

L1: /* within: to */
if (!(frame.tend.d[1].vword.integr <= frame.tend.d[2].vword.integr) )
    goto L2 /* bound */;
frame.tend.d[0].vword.integr = frame.tend.d[1].vword.integr;

```

```

    frame.tend.d[0].dword = D_Integer;
    P01_p(&frame.tend.d[0]);
    goto L4 /* end suspend: to */;
L4: /* end suspend: to */
    ++frame.tend.d[1].vword.integr;
    goto L1 /* within: to */;
L2: /* bound */

```

This is an example of a generator within an every expression being converted into an in-line loop. Except for the fact that descriptors are being used instead of C integers, this is nearly as good as the C code

```

for (i = 1; i <= 10; ++i)
    p(i);

```

## 22.5 Parameter Passing Optimizations

As mentioned above, parameter-passing optimizations are used to improved the generated code. These optimizations involve eliminating unneeded argument computations and eliminating unnecessary copying. These optimizations are applied to tailored in-line code. They must take into account how a parameter is used and whether the corresponding argument value has an extended lifetime.

In some situations, a parameter is not used in the tailored code. There are two common circumstances in which this happens. One is for the first operand of conjunction. The other occurs with a polymorphous operation that has a type-specific optional parameter. If a different type is being operated on, the optional parameter is not referenced in the tailored code. If a tailored operation has an unreferenced parameter and the invocation has a corresponding argument expression, the compiler notes that the expression result is discarded. Earlier in this chapter there are examples of optimizations possible when expression results are discarded. If the corresponding argument is missing, the compiler refrains from supplying a null value for it. Consider the invocation

```
insert(x, 3)
```

insert takes three arguments. If x is a table, the third argument is used as the entry value and must be supplied in the generated code. In the following generated code, the default value for the third argument is computed into frame.tend.d[2].dword:

```

frame.tend.d[1].dword = D_Integer;
frame.tend.d[1].vword.integr = 3;
frame.tend.d[2].dword = D_Null;
frame.tend.d[3] = frame.tend.d[0] /* x */;
F1o0_insert(&(frame.tend.d[2]), &(frame.tend.d[1]), &(frame.tend.d[3]),
    &trashcan);

```

Because F1o0\_insert uses a tailored calling convention, its arguments can be in a different order from those of the Icon function. It appears that the argument expression *x* is computed in the wrong place in the execution order. However, this is not true; the expression is not computed at all. If it were, the result would be a variable reference. Instead, the assignment of the value in *x* to the temporary variable is a form of optimized dereferencing. Therefore, it must be done as part of the operation, not as part of the argument computations. This is explained below.

If the value of *x* in this expression is a set instead of a table, the entry value is not used. This is illustrated by the following code. Note that a different C function is called for a set than for a table; this is because a different body statement is selected.

```

frame.tend.d[1].dword = D_Integer;
frame.tend.d[1].vword.integr = 3;
frame.tend.d[2] = frame.tend.d[0] /* x */;
F1o1_insert(&(frame.tend.d[1]), &(frame.tend.d[2]), &trashcan);

```

In general, an operation must copy its argument to a new descriptor before using it. This is because an operation is allowed to modify the argument. Modification of the original argument location is not safe in the presence of goal-directed evaluation. The operation could be re-executed without recomputing the argument. Therefore, the original value must be available. This is demonstrated with the following expression.

```
every p(0 to (1 to 3))
```

This is a double loop. The outer to expression is the inner loop, while the inner to expression is the outer loop. *to* modifies its first argument while counting. However, the first argument to the outer *to* has an extended lifetime due to the fact that the second argument is a generator. Therefore, this *to* operator must make a copy of its first argument. The generated code for this *every* expression is

```

frame.tend.d[2].dword = D_Integer;
frame.tend.d[2].vword.integr = 0;
frame.tend.d[4].dword = D_Integer;
frame.tend.d[4].vword.integr = 1;

```

```

    frame.tend.d[5].dword = D_Integer;
    frame.tend.d[5].vword.integr = 3;
L1: /* within: to */
    if (!(frame.tend.d[4].vword.integr <= frame.tend.d[5].vword.integr))
        goto L2 /* bound */;
    frame.tend.d[3].vword.integr = frame.tend.d[4].vword.integr;
    frame.tend.d[3].dword = D_Integer;
    frame.tend.d[6] = frame.tend.d[2];
L3: /* within: to */
    if (!(frame.tend.d[6].vword.integr <= frame.tend.d[3].vword.integr))
        goto L4 /* end suspend: to */;
    frame.tend.d[1].vword.integr = frame.tend.d[6].vword.integr;
    frame.tend.d[1].dword = D_Integer;
    P01_p(&frame.tend.d[1]);
    ++frame.tend.d[6].vword.integr;
    goto L3 /* within: to */;
L4: /* end suspend: to */
    ++frame.tend.d[4].vword.integr;
    goto L1 /* within: to */;
L2: /* bound */

```

The first argument to the outer to is copied with the statement

```
frame.tend.d[6] = frame.tend.d[2];
```

The copying of the other arguments has been eliminated because of two observations: the second argument of to is never modified and the first argument of the inner to (outer loop) is never reused without being recomputed. This second fact is determined while the lifetime information is being calculated. There is no generator occurring between the computation of the argument and the execution of the operator. Even if there were, it would only necessitate copying if the generator could be resumed after the operator started executing.

As noted above, another set of optimizations involves deferencing named variables. If an operation needs only the dereferenced value of an argument and type inferencing determines that the argument is a specific named variable (recall that each named variable is given a distinct variable reference type), the code generator does not need to generate code to compute the variable reference, because it knows what it is. That is, it does not need the value of the argument. If the argument is a simple identifier, no code at all is generated for the argument.

As shown in the code presented above for

```
insert(x, 3)
```

dereferencing can be implemented as simple assignment rather than a call to the `deref` function:

```
frame.tend.d[3] = frame.tend.d[0] /* x */;
```

In fact, unless certain conditions interfere, the variable can be used directly as the argument descriptor and no copying is needed. This is reflected in the code generated in a previous example:

```
if /x then ...
```

x is used directly in the in-line code for /:

```
if ((frame.tend.d[0] /* x */).dword == D_Null)
    goto L2 /* bound */;
```

This optimization cannot be performed if the operation modifies the argument, nor can it be performed if the variable's value might change while the operation is executing. Performing the optimization in the presence of the second condition would violate the semantics of argument dereferencing. The compiler does two simple tests to determine if the second condition might be true. If the operation has a side effect, the compiler assumes that the side-effect might involve the named variable. Side effects are explicitly coded in the abstract type computations of the operation. The second test is to see if the argument has an extended lifetime. The compiler assumes that the variable might be changed by another operation during the extended lifetime (that is, while the operation is suspended).

## 22.6 Assignment Optimizations

The final set of invocation optimizations involves assignments to named variables. These includes simple assignment and augmented assignments. Optimizing these assignments is important and optimizations are possible beyond those that can easily be done working from the definition in the data base; assignments to named variables are treated as special cases. The optimizations are divided into the cases where the right-hand-side might produce a variable reference and those where it produces a simple Icon value.

There are two cases when the right-hand-side of the assignment evaluates to a variable reference. If the right-hand-side is a named variable, a dereferencing optimization can be used. Consider

```
s := s1
```

This Icon expression is translated into

```
frame.tend.d[0] /* s */ = frame.tend.d[1] /* s1 */;
```

This is the ideal translation of this expression. For other situations, the `deref` function must be used. For example the expression

```
s := ?x
```

is translated into

```

if (O0f2_random(&(frame.tend.d[0] /* x */), &frame.tend.d[2]) == A_Resume)
    goto L1 /* bound */;
deref(&frame.tend.d[2], &frame.tend.d[1] /* s */);

```

When the right-hand-side computes to a simple Icon value, the named variable on the left-hand-side can often be used directly as the result location of the operation. This occurs in the earlier example

```
a := ~x
```

which translates into

```
O160_compl(&(frame.tend.d[0] /* x */), &frame.tend.d[1] /* a */);
```

This optimization is safe as long as setting the result location is the last thing the operation does. If the operation uses the result location as a work area and the variable were used as the result location, the operation might see the premature change to the variable. In this case, a separate result location must be allocated and the Icon assignment implemented as a C assignment. String concatenation is an example of an operation that uses its result location as a work area. The expression

```
s := s1 || s
```

is translated into

```

if (StrLoc(frame.tend.d[1] /* s1 */) + StrLen(frame.tend.d[1] /* s1 */)
    == strfree )
    goto L1 /* within: cater */;
StrLoc(frame.tend.d[2]) = alcstr(StrLoc(frame.tend.d[1] /* s1 */),
    StrLen(frame.tend.d[1] /* s1 */));
StrLen(frame.tend.d[2]) = StrLen(frame.tend.d[1] /* s1 */);
goto L2 /* within: cater */;
L1: /* within: cater */
    frame.tend.d[2] = frame.tend.d[1] /* s1 */;
L2: /* within: cater */
    alcstr(StrLoc(frame.tend.d[0] /* s */), StrLen(frame.tend.d[0] /* s */));
    StrLen(frame.tend.d[2]) = StrLen(frame.tend.d[1] /* s1 */) +
        StrLen(frame.tend.d[0] /* s */);

    frame.tend.d[0] /* s */ = frame.tend.d[2];

```

`frame.tend.d[2]` is the result location. If `frame.tend.d[0]` (the variable `s`) were used instead, the code would be wrong.

There are still some optimizations falling under the category covered by this chapter to be explored as future work. For example, as shown earlier,

$$a := \sim x$$

is translated into

```
frame.tend.d[2] = frame.tend.d[0] /* x */;
cnv_tcset(&(frame.cbuf[0]), &(frame.tend.d[2]), &(frame.tend.d[2]));
O160_compl(&(frame.tend.d[2]) , &frame.tend.d[1] /* a */);
```

when `x` is a string. The assignment to `frame.tend.d[2]` can be combined with the conversion to produce the code

```
cnv_tcset(&(frame.cbuf[0]), &(frame.tend.d[0] /* x */), &(frame.tend.d[2]));
O160_compl(&(frame.tend.d[2]) , &frame.tend.d[1] /* a */);
```

There is, of course, always room for improvement in code generation for specific cases. However, the optimizations in this chapter combine to produce good code for most expressions. This is reflected in the performance data presented in Chapter 23.

# Chapter 23

## Performance of Compiled Code

The performance of compiled code is affected by the various optimizations performed by the compiler. This chapter demonstrates the effects of these optimizations on the execution speed of Icon expressions. It also presents speed improvements and memory usage for compiled code versus interpreted code for a set of complete Icon programs. All timing results used in this chapter were obtained on a Sun 4/490 and are the average of the results from three runs.

### 23.1 Expression Optimizations

The effects of four categories of optimization are demonstrated. These are assignment optimizations, invocation optimizations, control flow optimizations, and optimizations using information from type inferencing. Expression timings for the first three categories were made using techniques described in the August 1990 issue of *The Icon Analyst* [.ian11.]. The following program skeleton is used to construct the programs to perform these timings.

```
procedure main()
  local x, start, overhead, iters
  iters := 1000000
  start := &time
  every 1 to iters do {
    }
  overhead := &time - start
  x := 0
  start := &time
  every 1 to iters do {
    expression to be timed (may use x)
  }
  write(&time - start - overhead)
```

end

The timings are performed both with and without the desired optimizations, and the results are compared by computing the ratio of the time without optimization to the time with optimization.

The assignment optimizations are described in Chapter 22. The effect of the assignment optimizations on the expression

`x := &null`

is measured using the program outlined above. The analysis that produces the assignment optimization is disabled by enabling debugging features in the generated code. The only other effect this has on the assignment expression is to insert code to update the line number of the expression being executed. In this test, the line number code is removed before the C code is compiled, insuring that the assignment optimization is the only thing measured. The timing results for this test produce

Assignment Test		
Time in Milliseconds Averaged over Three Runs		
Unoptimized	Optimized	Ratio
1122	478	2.3

The tests were performed with type inferencing enabled. Therefore, even the "unoptimized" version of the assignment has the standard operation optimizations applied to it. This test demonstrates the importance of performing the special-case assignment optimizations.

The next category of optimization measured is invocation optimization. This results in the direct invocation of the C functions implementing operations, or in some cases results in the operations being generated in line. The execution time for the expression

`tab(0)`

is measured with and without invocation optimizations. As with the assignment optimizations, these optimizations are disabled by enabling debugging features. Once again the line number code is removed before the C code is compiled. These optimizations interact with the optimizations that use information from type inferencing. The measurements are made with type inferencing disabled. Therefore, no type checking simplifications are performed. Without the invocation optimizations, the generated code consists of an indirect invocation through the global variable `tab`. With the invocation optimizations, the generated code consists of type checking/conversion code for the argument to `tab` and a call to the function implementing the body statement of `tab`. The timing results for `tab(0)` produce

## Invocation Test

Time in Milliseconds Averaged over Three Runs

Unoptimized	Optimized	Ratio
8394	4321	1.9

The third category of optimization is control flow optimization. As explained in Chapter 21, these optimizations only perform improvements that a C compiler will not perform when the code contains trivial call chains. One situation that produces trivial call chains is nested alternation. The execution time for the expression

```
every x := ixor(x, 1 | 2 | 3 | 4 | 5)
```

is measured with and without control flow optimizations. The timing results for this every loop produce

## Control Flow Test

Time in Milliseconds Averaged over Three Runs

Unoptimized	Optimized	Ratio
6384	4184	1.5

The final category of optimization results from type inferencing. The speed improvements result from generating operations in line, eliminating type checking, and generating success continuations in line. Use of the `to` operation is a good example of where these optimizations can be applied. This is demonstrated by measuring the speed of an every loop using the `to` operation. The program that performs the measurement is

```
procedure main()
  local x, start
  start := &time
  every x := 1 to 5000000
  write(&time - start)
end
```

The timing results for this program produce

## Type Inference Test

Time in Milliseconds Averaged over Three Runs

Unoptimized	Optimized	Ratio
9233	2721	3.3

Another approach to determining the effectiveness of type inferencing is to measure how small a set it deduces for the possible types of operands to operations. This indicates whether future work should concentrate on improving type inferencing itself or simply concentrate on using type information more effectively in code generation. A simple measure is used here: the percentage of operands for which type inferencing deduces a unique Icon type. Measurements are made for operands of all operators, except optimized assignment, and for operands of all built-in functions appearing in optimized invocations. For the most part, these are the operations where the code generator can use type information. Measurements were made for a set of 14 programs (described below). Unique operand types within each program range from 63 percent to 100 percent of all operands, with an overall figure for the tests suite of 80 percent (this is a straight unweighted figure obtained by considering all operands in the test suite without regard to what program they belong to); even a perfect type inferencing system will not deduce unique types for 100 percent of all operands, because not all operands have unique types. This suggests that an improved type inferencing system may benefit some programs, but will have only a small overall impact. Future work should give priority to making better use of the type information rather than to increasing the accuracy of type inferencing.

## 23.2 Program Execution Speed

It has been demonstrated that the compiler optimizations are effective at improving the kinds of expressions they are directed toward. The question remains: How fast is compiled code (with and without optimizations) for complete programs as compared to interpreted code for the same programs? For some expressions, optimizations may interact to create significant cumulative speed improvements. For example, the fully optimized code for the every loop in the previous example is 30 times faster than the interpreted code; the improvement of 3.3 from type inferencing contributes one factor in the total improvement. Other expressions may spend so much time in the run-time system (which is unaffected by compiler optimizations) that no measurable improvements are produced.

A set of 14 programs was selected mostly from contributions to the Icon program library [.tr90-7.] for testing the performance of the compiler. These programs were selected to represent a variety of applications and programming styles (an additional requirement is that they run long enough to obtain good timing results).

The following table shows the speed improvements for the compiled code as compared to interpreted code. The compiler and interpreter used for the measurements both implement Version 8 of Icon. The execution time used to compute the speed improvements is the cpu time measured using the Bourne shell's time command. The first column in the table shows the execution time under the interpreter. The second column is for compiled code with debugging features enabled and optimizations disabled. This code is still better than what would be obtained by just removing the

interpreter loop, because intelligent code generation is performed, especially for bounded expressions, and keywords are generated in line. The third column is for code with debugging features disabled and full optimization enabled.

Execution Time in Seconds Averaged over Three Runs

Program	Interpreter	Compiler	
		Unoptimised	Optimized
cksol	49.9	33.5 (1.48)	22.5 (2.21)
concord	31.1	18.5 (1.68)	9.8 (3.17)
iidecode	60.3	34.0 (1.77)	12.9 (4.67)
iiencode	50.4	34.4 (1.46)	10.5 (4.80)
impress	44.6	24.8 (1.79)	14.0 (3.18)
list	43.1	24.5 (1.75)	13.6 (3.16)
memfiltr	60.8	34.3 (1.77)	15.3 (3.97)
mf	30.1	18.7 (1.60)	14.7 (2.04)
pssplit	64.0	39.0 (1.64)	26.6 (2.40)
roffcmds	32.9	18.1 (1.81)	12.0 (2.74)
sentence	34.3	23.9 (1.43)	16.2 (2.11)
spandex	36.8	23.3 (1.57)	14.7 (2.50)
textcnt	36.2	18.4 (1.96)	9.9 (3.65)
wrapper	27.3	15.9 (1.71)	9.4 (2.90)

The numbers in parentheses are speed-up factors obtained by dividing the interpreter execution time by the execution time of compiled code.

## 23.3 Code Size

One advantage the compiler has over the interpreter is that, unless a program is compiled with full string invocation enabled, the executable code for a program need not include the full run-time system. For systems with limited memory, this can be a significant advantage.

The sizes of executable code presented here are obtained from file sizes. All executable files have had debugging information stripped from them. The size of the executable code in the interpreter system is taken to be the size of the interpreter (278,528 bytes) plus the size of the icode for the program being measured (under Unix systems, the size of the executable header, 12,800 bytes for the Sun 4, is subtracted from the size of the icode file, because it is not present during interpretation). Measurements for the 14 test programs are:

Program Sizes in Bytes			
Program	Interpreter	Compiler	Ratio
cksol	282,153	81,920	0.29
concord	284,416	90,112	0.31
iidecode	285,525	98,304	0.34
iiencode	283,567	81,920	0.28
impress	295,656	114,688	0.38
list	287,376	98,304	0.34
memfiltr	296,082	114,688	0.38
mf	282,739	81,920	0.28
pssplit	279,709	73,728	0.26
roffcmds	280,797	81,920	0.29
sentence	283,249	81,920	0.28
spandex	281,843	81,920	0.29
textcnt	280,397	73,728	0.26
wrapper	279,780	73,728	0.26

Other factors create differences in memory usage between the interpreter and compiled code. For example, the interpreter allocates a stack for expression evaluation. On the Sun 4, this stack is 40,000 bytes. The compiler, on the other hand, allocates work areas on a per-procedure basis and only allocates the maximum needed at any execution point within the procedure.

# Chapter 24

## Scalable Type Inferencing

Authors: Michael Wilder, Anthony Jones and Clinton Jeffery

This chapter details compile-time space savings in `iconc` that enable it to handle large Unicon programs. The Icon compiler represents all the possible types as a bit vector with each bit position representing a specific type. Such vectors are required for each variable including each temporary variable location as a result of subexpression evaluation. The type inferencing model allocates a unique type to each source location at which heterogeneous structure types such as lists or records are created. In the course of compiling a large program, the number of total types, and therefore the size of the bit vectors, can skyrocket. According to Walker [Walker93], the type inferencer described in Chapters 15 and 19 has a space cost of  $O(n^3)$ . The associated constants, and the value of  $n$ , may be large. Improving the memory usage of `iconc`'s type inferencing system was necessary because the compiler was empirically observed to run out of memory compiling large programs.

At the time it was developed, `iconc` was able to compile small to medium size Icon programs. Although main memories in typical computers have increased from 4MB to 4GB in the years since `iconc` was developed, Unicon programs can be much larger than Icon programs. Likewise, heavily object-oriented programs, such as ones with graphical user interfaces, are especially demanding for the type inferencer, as they introduce large numbers of new types. For these reasons, the space needed for type inferencing was a problem that demanded attention and limited the applicability of the optimizing compiler.

In 1996 Anthony Jones introduced compact representations that reduced space requirements by approximately a factor of 3 [Jones96], providing enough relief to allow `iconc` to compile some larger programs of the time. These improvements were subsumed a decade later by the work described in this chapter. After realizing that type information was frequently duplicated, a type vector hashing scheme was introduced by which almost all redundant allocations of type information were avoided. This work effectively solved the memory space scalability problem for type inferencing.

## 24.1 The Type Representation

One way to reduce space requirements is to optimize the representation of type information. Iconc maintains a structure for each variable that contains information about that variable, including a bit vector with each bit representing a particular type used in the program. When a bit vector is allocated it is one of three possible sizes. The first size is composed of first class types which are those built in types plus user defined types that are utilized. The second size consists of the first class types plus intermediate value types. Lastly, there is the number of total types in the database. The database refers to the collection of all builtin operations, their number of parameters and types, and the type for the return value.

Data was gathered from *Ctree*, a circular tree visualization tool. This program consists of ~500 lines of source code. The number of possible first class types is 209 which translates to a 28 byte bit vector. Note that bit vectors are allocated in multiples of a word (4 bytes). During the course of the compilation, 137,946 bit vectors are allocated. The number of first class types plus types for intermediate values is 1,012, resulting in a 128 byte bit vector, and 18,925 vectors of this size are allocated. Lastly, the number of database types is 1,369 types, using a 172 byte bit vector with only 121 allocations of this size. The total memory requirement for the bit vectors is 6.22 megabytes. This information is summarized in Figure 24-1.

<i>Vector Type</i>	<i>Number of Types</i>	<i>Number Allocated</i>	<i>Required Memory (MB)</i>
first class	209	137946	3.8
intermediate class	1012	18925	2.4
database class	1369	121	0.02

Figure 24-1: Bit Vector Sizes

Figure 24-2 is an example of what a bit vector from *Ctree* might look like. This example shows the division between the three type classes. Within the partition for first class types is bit 0 which represents an integer and bit 6 which is a real. Within the intermediate types partition, bit 209 represents an instance of a *cnode* record and an instance of a list variable, and bit 232 is an instance of a variable that is of the list type. Every instance of a list or an aggregate type such as a record results in a new type that gets its own bit in the bit vector.

Lastly, within the database class are builtin operations. The functions for random number (*O0z7\_random*) and subtraction (*O114\_subc*) are assigned bits 1,012 and 1,368 respectively. The functions are builtin to the Icon compiler and are assigned their own types in the bit vector.

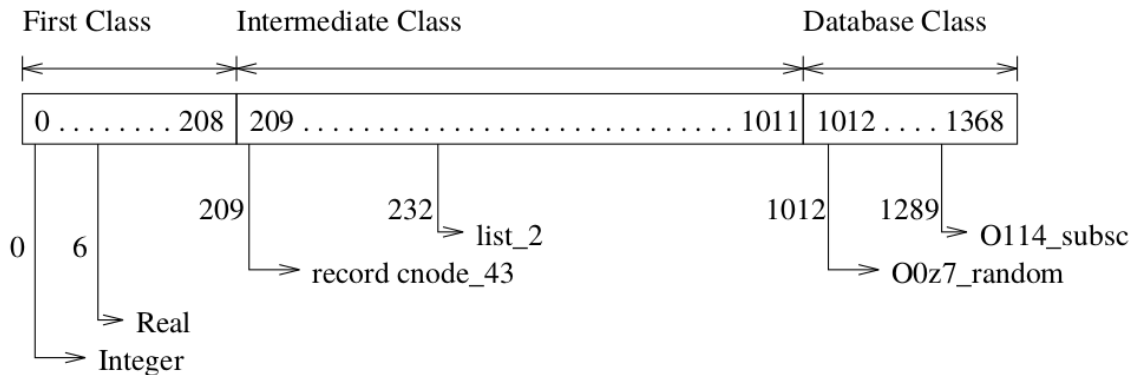

Figure 24-2: Sample Bit Vector

Additional tests were run on a 25,000 line Icon (really Idol) program called *Freedom in the Galaxy*, which was a semester long effort by Dr. Jeffery's Software Engineering class. The program has hundreds of variables, but object-orientation requires many additional intermediate variables and dramatically increases the number and size of type vectors allocated during compilation. *Freedom in the Galaxy* has 12,591 different distinct types including builtin, intermediate, and database types. This is an example of a program that ran out of memory during compilation with iconc on typical workstations in the mid-1990's, motivating space improvements.

## 24.2 Type Vector Hashing

Type inferencing in iconc uses collections of large bit vectors that are frequently referenced. The bit vectors represent sets of possible types at each program point. This section presents an incremental technique that dramatically reduces the space required for these bit vectors. The technique depends on a classic data structure: the hash table.

Hash tables are used in many different application domains to map keys (usually small) onto (often much larger) values. In their degenerate form, hash tables can be used to store a set of keys, with no associated values. Such sets may be needed for purposes of memory sharing, as in the Flyweight design pattern. The traditional hash table  $O(1)$  average case lookup and insert speeds break down when the keys are very large (for example, hundreds of machine words) and heavily referenced (many millions or billions of lookups). In such circumstances, it is imperative to identify a fast hash function that performs well despite the large data keys to be hashed.

## 24.3 Type Inferencing

As mentioned previously, iconc's type inferencer originally required  $O(n^2)$  space on average and  $O(n^3)$  in the worst case, where  $n$  corresponds to program size (as a number of expressions, not

bytes or lines of code). The inferencer allocated large bit vectors at every (sub)expression point in a program where typed values are transmitted. This algorithm runs acceptably for small and medium size programs, but fails for large programs. For example, in one of the test programs, the brute force algorithm attempted to `malloc()` 24GB of memory, exceeding the capacity of the test machine. By the time such allocations are easily supported on most computers, larger Unicon programs will be written for which even more space will be needed. Type inferencing space requirements are exacerbated in object-oriented programs which may utilize many hundreds of user-defined types for classes and their method vectors.

## 24.4 A Copy-on-Write Type Vector Pool

Analysis revealed much redundancy among type vectors associated with type-mutable program points when inferring the types in programs. Hashing was introduced to eliminate type vector redundancy by employing copy-on-write semantics in a type vector pool. Using a hash table to implement a shared pool of bit vectors largely solves the space problem, reducing space needs to  $O(n)$  on average and  $O(n^2)$  in the worst case, at a potentially large cost in time. If the time constants involved increase the real-world time to an impractical extent, then the use of hashing fails despite its successful space reduction.

The hashing of type vectors in the type inferencer poses many challenges. The width of type vectors varies with the number of run-time types present in an input program. Type vectors in the type inferencer can be quite large because the run-time type information produced is of very high quality. For example, in addition to bits for all the base types and declared record or class types, the bit vector also must contain bits for each field (or member variable) of each class or record. The type inferencer also uses a separate bit in the vector to differentiate each constructor site for composite types (such as lists). A list containing strings, for instance, is assigned a different type than a list containing records or a list containing strings and records. This fine granularity of type information contributes admirably to the speedup of targets generated by the Unicon Compiler, but causes type vectors to become very large during type inferencing.

The number of vectors required for type inferencing depends upon the number of type-mutable program points in the dataflow graph of the input program. Some programs have many possible types, but contain relatively few type-mutable program points; other programs contain relatively few run-time types but have many type-mutable program points. And, of course, some programs contain many type-mutable program points and many possible run-time types. These variables exacerbate the requirements imposed upon a type vector hashing scheme. To add further interest, analysis of the bit patterns held in non-redundant type vectors within the type inferencer at compile-time revealed no reliable lever of disparity that could be employed as a collision reductive agent in a type vector hashing scheme.

## 24.5 Implementation

Implementation began with a software harness to permit the direct comparison of various hashing techniques within the specific confines of the Unicon Compiler type inferencer. Experimentation produced a fixed-address, multiplicative hashing scheme wherein the number of buckets in the hash table is a variant power of 2 greater than 255. This number varies depending upon characteristics of the input program ascertained before the start of type inferencing.

Type vectors are allocated from a pool of vectors that serves as the vector store during type inferencing. The size of this pool also varies depending upon characteristics of the input program ascertained before the start of type inferencing. The pool of vectors contained in the Unicon Compiler type inferencer is a discrete entity that is not accessed directly by the type vector hash table. This separation facilitates experimentation with different pooling algorithms and implementations without modifying the type vector hash table implementation. All pools in the Unicon Compiler type inferencer are implemented in this manner.

The vector hash table implementation in the Unicon Compiler does not permit the migration of type vectors among buckets in the hash table. Once a type vector is inserted into a hash table bucket, it remains in situ for the duration of type inferencing. Reference counts are not maintained for type vectors contained within the hash table because any type vector in the system (except one) is created as the result of a transformation applied to another type vector that already exists within the type vector hash table.

A tremendous savings of space during type inferencing was immediately realized by eliminating type vector redundancy through hashing. The initial space reductions obtained were comparable to those indicated in Section 5. Although adding a hash table increases the complexity and likewise increases the number of instructions required for type vector generation, eliminating type vector redundancy provided a speedup of some vector manipulation operations because we were able to employ reference-based vector equality comparisons where value-based comparisons were previously required.

### 24.5.1 Bit Vector Hashing

An early version of the vector hashing function employed in the Unicon Compiler type inferencer is depicted in Figure 24-6. Subsequent analysis and refinement of our hashing scheme produced a much faster method than this straightforward approach.

```

00. static
01. inline
02. unsigned int
03. hash(bits)
04.     unsigned int * bits;
```

```

05. {
06.     int i;
07.     unsigned long long rawhash, xor;
08.     unsigned int cookedhash;
09.
10.     rawhash = xor = 0ULL;
11.     i = n_rttyp_ints - 1;
12.     while (i >= 0) {
13.         rawhash += xor;
14.         rawhash += bits[i];
15.         xor ^= bits[i];
16.         i--;
17.     }
18.     rawhash *= 0x20c49ba5e353f7cfULL;
19.     i = hash_shifts;
20.     cookedhash = rawhash & hash_mask;
21.     while (i) {
22.         rawhash >>= hash_upper_shr;
23.         cookedhash ^= rawhash;
24.         i--;
25.     }
26.     return (cookedhash & hash_mask);
27. }

```

Figure 24-6: Hashing before halving

In function `hash()`, the cumulative `xor` is used to perturb the raw hash value. The variable `n_rttyp_ints` is the size of array in words; `hash_shifts` is the word size divided by the bucket size, and is used in order to ensure that the entire hash number is involved in bucket selection. The hex constant was derived experimentally to maximize distribution on a wide range of input bit vectors.

Having achieved a dramatic space reduction, the next step was to refine the hashing and pooling algorithms to improve the speed of type vector creation and retrieval during type inferencing.

### 24.5.2 Hash Halving

It is not uncommon to encounter type vectors that are well over 100 machine words wide when inferring the types of large programs. Locality is a major performance impediment when hashing type vectors in programs of this nature. The techniques described in this section were devised to improve the speed of type inferencing in the Unicon Compiler.

The hashing routine depicted in Figure 24-6 was employed in early space-reduction experiments

with the Unicon Compiler type inferencer. This hashing routine traverses the entire length of a type vector in order to compute its hash value. This conservative approach makes use of all the information contained within the bits of a type vector, but it becomes problematic when type vectors are hundreds of machine words wide and the hashing routine is invoked hundreds of millions of times during type inferencing. Approaches in which the hash function considers only a portion of the information in a type vector would hash faster, at the expense of more collisions. Instead, we conducted experiments to reduce the time required to compute the hash value of full type vectors. This experimentation produced a technique referred to as *hash halving*.

Hash halving permits the hashing of arbitrarily wide type vectors without traversing said vectors. To accomplish this, the hashing routine is split into a *top half* routine and *bottom half* routine. The top half routine performs a full traversal of a given type vector in order to produce a “raw” hash value for the vector. The bottom half routine is a scrambling function that transforms the raw hash value produced by the top half into a “cooked” hash value for the vector. Referring to the hashing routine in Figure 1, lines 10-17 constitute the top half and lines 18-26 constitute the bottom half of this routine. In a conventional hashing scheme, computing the hash value of a type vector would entail invoking the top half and bottom half hashing routines. The Unicon Compiler type inferencer does not do this.

It is immediately apparent that the bottom half of the hashing routine in Figure 24-6 is computationally much less expensive than the top half when type vectors are very wide. Lines 10-17 are executed in time proportional to the width of the type vector being hashed, which in the worst case is  $O(n)$ . Lines 18-26, on the other hand, are  $O(1)$  because the value of `hash_shifts` will never be larger than the width of a “raw” hash value. If, for instance, a raw hash value is represented in 64 bits and the hash table contains 256 buckets, the value of `hash_shifts` is initialized to 7 at the start of type inferencing. The intuition behind hash halving is to circumvent the computational expense of the top half whenever possible, thereby reducing the  $O(n)$  cost of the top half to an  $O(1)$  incremental cost whenever a type vector is modified. In the Unicon Compiler type inferencer, this is facilitated by the fact that all type vectors instantiated during type inferencing are descendants of a single type vector called the *genesis vector*.

At the start of type inferencing in the Unicon Compiler, there exists a single type vector in the system. This genesis vector represents the union of all types permissible in the input program. All type-mutable program points in the dataflow graph of the input program initially refer to this genesis vector because reference-based semantics are used and no refinement of information about the types at said program points has yet been accomplished. When the genesis vector is created at the start of type inferencing, the raw (top half) hash value for this vector is computed and stored as a datum with the vector. Any subsequent vectors produced as a result of some transformation of this genesis vector use the raw hash value stored in the genesis vector to compute what the raw hash value of the potentially new type vector would be, based upon the transformation applied to the genesis vector. This computation occurs without any knowledge of the actual content of the genesis vector.

The raw hash value associated with a type vector in the Unicon Compiler type inferencer is a simple summation (see Figure 24-7). This summation facilitates incrementality by permitting fast updating of the raw hash value of a vector when attempting to determine the raw hash value for a potentially new type vector.

For example, assume that some type-mutable program point contains a reference to the genesis vector  $V_G$ . In the event that the type inferencer wants to apply transform  $t_1$  to  $V_G$ , it is desirable to determine whether the result of this transformation ( $V_1$ ) is already a member of the vector hash table without performing a full hash of  $V_1$ . The Unicon Compiler type inferencer accomplishes this as follows.

The raw hash value of  $V_G$  is copied into a temporary vector. This raw hash value is then transformed *in place* based upon the nature of the transform  $t_1$  to produce the raw hash value of the subject vector  $V_1$ . This circumvents a call to the top half hashing routine. The type inferencer then invokes the bottom half hashing routine to transform the raw hash value of  $V_1$  into the cooked hash value of  $V_1$ . If the vector hash table bucket corresponding to the cooked hash value of  $V_1$  is empty,  $V_1$  of course does not exist in the hash table. The temporary vector is populated with the content of the vector  $V_G$ , the contents of the temporary vector are transformed via  $t_1$ , and the temporary vector is inserted into the vector hash table to become  $V_1$ .

In the event that the vector hash table bucket corresponding to the cooked hash value of the subject vector  $V_1$  is not empty, the temporary vector is populated with the characteristics of  $V_1$  and the hash table bucket is searched for the subject vector  $V_1$ .

```
static inline unsigned long long hash_th(bits)
    unsigned int * bits;
{
    int i;
    unsigned long long h;
    h = 0ULL;
    i = n_rttyp_ints - 1;
    while (i > 0) {
        h += bits[i] * i;
        i--;
    }
    h += bits[0];
    return h;
}
```

Figure 24-7: Top Half Vector Hashing Routine

It should be noted that if  $V_1$  is indeed not a member of the vector hash table, its raw hash value has already been computed and any subsequent transformations of  $V_1$  to produce some vector  $V_2$

can be treated in the same manner as described above. To convey an idea of the useful nature of this technique, there are 12 type vector mutator routines in the Unicon Compiler type inferencer. In all of these mutators, type vector transformations occur without invoking the top half hashing routine.

An example of how the Unicon Compiler updates the raw hash value of a vector when setting a bit in a type vector appears in Figure 24-8. The simple arithmetic operations required to perform this update are the intentional result of choosing a top half hashing routine that maximizes the performance of incrementality. Thanks to the modulo-based ring semantics of unsigned integer arithmetic, the previous summation term can be subtracted out and the new term can be added in correctly even in the presence of integer overflow and underflow.

```
n = idx ? idx : 1;
vect->raw_hash -= vect->bits[idx] * n;
vect->bits[idx] |= bit_mask;
vect->raw_hash += vect->bits[idx] * n;
```

Figure 24-8: Updating a Raw Hash Value

The nature of the top half hashing routine is of paramount importance when performing hash halving. The top half hashing routine must be selected such that it contains logic simple enough to facilitate the in-place manipulation of the raw hash value of some vector  $V_n$  to produce the raw hash value of vector  $V_{n+1}$  based upon a vector transformation  $t$  applied to vector  $V_n$  with no a priori knowledge of the actual content of vector  $V_n$ . An implicit requirement in this pursuit is bi-directionality of operation: both the setting and clearing of bits in a vector must be computationally expedient.

The top half vector hashing routine currently used in the Unicon Compiler type inferencer is depicted in Figure 24-7. In this figure, the value of `n_rttyp_ints` is computed before the start of type inferencing and remains constant thereafter. The top half hashing routine depicted in this figure is extraordinarily simple. This simplicity is of the highest importance because the logic in this routine is inlined wherever a bit vector is mutated during type inferencing, and is executed hundreds of millions of times during the course of type inferencing.

The bottom half hashing routine must transform the raw hash value supplied by a top half into a cooked hash value that contributes to a smooth distribution of vectors over hash table buckets. The bottom half must also be as fast as possible because it will be invoked hundreds of millions of times during type inferencing. The bottom half vector hashing routine currently used in the Unicon Compiler type inferencer is depicted in Figure 24-9. In this figure, the values of `hash_shifts`, `hash_mask`, and `hash_upper_shr` are computed before the start of type inferencing and remain constant thereafter. The bottom half hash routine depicted in Figure 24-9 runs in time  $O(1)$ .

```

static inline unsigned int hash_bh(raw)
    unsigned long long raw;
{
    int i;
    unsigned int u;
    raw *= 0x20c49ba5e353f7cfULL;
    i = hash_shifts;
    u = raw & hash_mask;
    while (i) {
        raw >>= hash_upper_shr;
        u ^= raw;
        i--;
    }
    return u & hash_mask;
}

```

Figure 24-9: Bottom Half Vector Hashing Routine

## 24.6 Metrics

All measurements in this section were taken on a dual-processor, dual-core, 1.8GHz AMD64 machine with 4GB core running Fedora Core 3 Linux because the sponsor is running Fedora. A program called `cls-gen` was used to generate all the programs that are used to measure type inferencing space and time usage in the following metrics. The `cls-gen` program is a program that generates programs. This program takes a numeric parameter `n` and creates files containing `n` class declarations and a single `main()` procedure. The generated `main()` procedure creates a list that is populated with a single instance of each of the `n` classes. The `main()` procedure then enters a loop in which all methods contained in each of the `n` class instances is invoked.

Versions 076 and 0c5 of the Unicon Compiler are compared in the metrics contained in this section. Version 076 of the Unicon Compiler is the last version that does not use vector hashing. Version 0c5 of the Unicon Compiler is the first version that uses vector hashing, hash halving, and vector auras.

### 24.6.1 Space

The space consumed during type inferencing in versions 076 and 0c5 of the Unicon Compiler are compared in Figure 24-10 below.

<i># types</i>	<i>V076</i>	<i>V0c5</i>
416	1.3 MB	26 KB
864	13.1 MB	129 KB
1,676	85 MB	454 KB
3,276	649 MB	1.7 MB
4,876	2.6 GB	3.9 MB
6,476	5.0 GB	6.9 MB

Figure 24-10: Type Inferencing Space Usage

The reader will note that in the type inferencing space comparison, v076 always consumes at least an order of magnitude more space than v0c5. A program containing 500 run-time types is considered a fairly small (but not tiny) program in this language.

## 24.6.2 Time

The time consumed during type inferencing in versions 076 and 0c5 of the Unicon Compiler are compared below.

<i># types</i>	<i>V076</i>	<i>V0c5</i>
416	.040	.038
864	.588	.549
1,676	6.6	3.6
3,276	101.6	25.4
4,876	524.4	82.8
6,476	1512	198

Figure 24-11: Type Inferencing Times (seconds)

The type inferencing time comparison contained in Figure 24-11 reveals a couple noteworthy points. Version v0c5 takes about the same time to infer the types in small programs such as that containing 416 run-time types. This is despite the fact that v076 allocates all type vectors at the start of type inferencing, whereas v0c5 contains extra logic to pool type vectors and replenish the pool when it is exhausted. Tailoring of the vector pool allocation algorithm might further improve the performance reported in v0c5.

The second point of note regarding Figure 24-11 is that v076 of the Unicon Compiler type inferencer consumes more memory than is present in the system when inferring the types in a program containing 6,476 types. Some of the time represented in the last entry is swapping. Enhancing the scalability of the type inferencer, and thus avoiding such swapping, was one of the primary motivations for implementing type vector hashing. A comparison of the inferencing times for v076 and v0c5 on programs containing more types than those depicted in Figure 24-11 would only serve to illustrate the grisly divergence provoked by swapping as physical memory is exhausted.

### 24.6.3 Measuring the Techniques

This section examines the contribution that each of the techniques described in this paper makes to reducing the overall time to infer types in large programs. Three instances of the compiler were created and labeled A, B, and C. Instance A is a basis point that contains only vector hashing. Instance B contains vector hashing and hash halving. Instance C contains vector hashing, hash halving, and vector auras. The time required to perform type inferencing on three programs was measured in each of these individual instances and appears in Figure 24-12.

<i># types</i>	<i>A</i>	<i>B</i>	<i>C</i>
3,276	364.6 s	63.7 s	30.3 s
4,876	1847.4 s	287.0 s	107.2 s
6,476	6,319.9 s	800.8 s	246.0 s

Figure 24-12: Type Inferencing Time Per Technique

Each row of Figure 24-12 shows the contribution of the hash halving and vector aura techniques to the speedup of type inferencing in the Unicon Compiler. This data shows that, when using a conventional hash table, the dramatic savings in space is achieved at an unacceptable cost in time, compared with the brute force, non-hashing, highly redundant implementation in v076. The reader will note that, when comparing the A column in Figure 24-12 with the v076 column in Figure 24-11, the A instance of the Unicon Compiler takes a factor of 3 or more time to perform type inferencing than the v076 version of the Unicon Compiler in the programs indicated in these figures. Type vector hashing using conventional techniques is clearly insufficient in terms of time.

The data in Figure 24-12 indicate that hash halving (B) contributes admirably to type inferencing speedups in the Unicon Compiler. The smallest speedup gained by adding hash halving to the Unicon Compiler type inferencer in this set of measurements is roughly 82%. Eliminating type vector redundancy by hashing type vectors provides a significant space improvement, but the hash halving technique makes type vector hashing practical in terms of time.

The vector aura technique (C) in these measurements provides at least a 60% reduction in type inferencing time. Vector auras are checksums stored in hash table entries to avoid comparing long data values in the event of collisions; we have experimented with several kinds of auras. If the hash function is good the hash number itself makes a good aura. Especially fast hash functions may benefit from different auras.

#### 24.6.4 Collision Rates

In this section we examine the expected rate of collisions in the vector hash table contained in the Unicon Compiler type inferencer. The expected value rate of hashing collisions is shown for the Unicon Compiler v0c5, the version that employs vector hashing, hash halving, and vector auras.

<i># types</i>	<i>M</i>	<i>N</i>	<i>collision rate</i>
416	512	255	0.003922
864	1024	507	0.001972
1,676	2048	1,152	0.000868
3,276	8192	4,377	0.000228
4,876	16384	6,527	0.000153
6,476	16384	8,677	0.000115

Figure 24-13: Vector Hash Table Collisions

In Figure 24-13 the rate of collisions within the vector hash table is shown for each of the programs depicted in section 24.6. As mentioned previously, the number of buckets in the vector hash table (*M*) is calculated before the start of type inferencing based upon information gleaned from the input program. The number of vectors contained within the hash table is represented by *N*. Type vectors are never removed from the vector hash table once they are added, so *N* in Figure 24-13 represents the number of type vectors in the hash table at the termination of type inferencing.

Figure 24-13 indicates that the expected rate of collisions in the type vector hash table decreases as the number of types in an input program increases. Rows 5 and 6 of this figure are particularly interesting in that the number of buckets in the vector hash table remains the same for each of the programs, but the collision expectation rate decreases as the number of the vectors present in the hash table increases. One hypothesis for this behavior is that the type vectors contained within the hash table for the program run in row 6 are less sparse. The bottom half hash routine in the Unicon Compiler type inferencer (see Figure 24-9) employs *xor* as its primary operator, and this form of perturbation tends to favor vectors that are more densely populated with bits that are set.

Measurements of the expected rate of collisions when using the “full” hashing routine appearing in Figure 24-6 were also taken. The collision rate produced by this routine is statistically insignificant from the expected value of collisions appearing in Figure 24-13.

To illustrate the scalability of the Unicon Compiler type inferencer, the time and space consumed by the Unicon Compiler v0c5 while inferring the types in a very large program containing 9,676 run-time types was measured, and the time and space consumed by gcc when compiling the C code generated by the Unicon Compiler for this same program was measured. The Unicon Compiler v0c5 consumed 1GB of memory to infer the types in this program. At the apex of its memory consumption, gcc used roughly 4GB. The Unicon Compiler consumed 13.9 minutes to infer the types in the program, and gcc consumed roughly 23.1 minutes to compile the resulting C code (not including `as` or `ld`.) In large programs, type inferencing no longer dominates total compile time. Prior to the start of this work, the Unicon Compiler v076 attempted to allocate 24GB of core at the start of type inferencing when presented with this same program. On the test machine, this results in a kernel panic before completing a single iteration of type inferencing.

## 24.7 Conclusions

The hashing of type vectors in the Unicon Compiler type inferencer has proven to be an effective technique for decreasing the space required to infer types used in all programs. We have shown in this paper that vector hashing results in space savings of multiple orders of magnitude when inferring the types in large input programs. Given the urgent need for vector hashing, the hash halving technique provides a significant speedup of the type inferencer by eliminating the need to traverse a type vector in order to compute its hash value. This speedup is particularly evident when type vectors are very wide. The speedup realized by providing the aura of a type vector to act as a filtering mechanism when searching a hash table bucket for a given vector is also meaningful, given that implementing type vector auras is straightforward.

Although we are pleased with the space savings described in this paper, global type inferencing remains a space challenge. One recent real-world example required 600,000 unique type vectors in the hash table. With each vector on the order of 1600 bytes, type inferencing alone still requires ~1GB for this program; larger examples exist. This motivates further reductions in type inferencing space requirements.

Despite substantial time improvements, we remain dissatisfied with the time required to infer the types in programs containing thousands of run-time types. We have broadened the domain of applications for which the Unicon Compiler is a viable tool, but further time-directed research is necessary. Additional type inferencing speedups may be obtainable by devising better hash halves, thereby improving the distribution of type vectors over hash table buckets, but other approaches are also needed. A trie (with edges based on type vector manipulations) superimposed on the vector hash table might reduce bit manipulation and hash function calls enough to overcome its additional

costs in terms of space and code complexity.

Experiments were conducted using sparse vectors to represent type vectors in very early space-directed experiments in the Unicon Compiler. The 67% space savings produced by sparse vector representation is largely subsumed by the greater space savings and space-complexity improvement provided by vector hashing. However, the techniques are not mutually exclusive and it may be possible to couple a sufficiently clever sparse representation of type vectors with the copy-on-write, reference-based semantics of type vector hashing (and hash halving) to further reduce the space and time consumed during type inferencing in the Unicon Compiler.

The techniques described in this section were devised by exploiting strengths and attacking weaknesses specific to the Unicon Compiler type inferencer. However, these techniques can be applied to other domains where large data is derived incrementally and must be hashed.

# Chapter 25

## Optimizing Code Generated by Iconc

Author: Anthony Jones

Since Ken Walker produced `iconc`, several optimizations have been implemented with the goal of improving execution time of the generated executable. The goals of these optimizations are to make the intermediate code as small as possible and to speed up the resulting executable. First a brief summary of the internal representation of the C code is provided. This is necessary because most of these optimizations rely heavily on analyzing the internal C code. Following this, the individual optimizations are discussed in detail.

There are different levels at which compiler optimizations may be performed. One level of optimization deals with the front end and intermediate code generation. Some examples of these optimizations include common subexpression elimination, copy propagation, dead-code elimination, constant folding, loop unrolling, and strength reduction. Another level of optimization is machine specific, including efficient register assignments, use of platform-specific instructions that offer greater performance, or doing peephole transformations [ASU86]. The optimizations implemented thusfar for the Icon compiler are not platform-specific because `iconc` translates Icon code into C code which then calls the native C compiler to finish the job.

### 25.1 Areas Where Iconc Can Be Improved

Iconc's compiled code is often many times faster than VM-interpreted code, but is far from optimal. The next few sections describe components of the existing compiler that were optimized by Anthony Jones and are now part of the Unicon language distribution.

An examination of Icon's generated intermediate C code suggested many areas of improvement. Some of the optimizations possible were eliminating redundant system calls, replacing Icon literals with C literals, and eliminating unnecessary logic in variable initialization blocks.

### **25.1.1 Redundant Function Calls**

A macro named `Poll()` is called every so often to handle certain system operations such as processing window system events. The `iconc` compiler initially did a naive job of placing these function calls in the generated code. Often there were two calls to `Poll()` one right after the other or only a simple assignment between two calls. The objective of this optimization is to remove the redundancy and let a reasonable number of calls remain.

### **25.1.2 Constant Propagation**

Simple literals appearing in source programs are assigned into the local variable descriptor table within a procedure. This descriptor table is an array of complicated structures and pointers that incurs many memory references simply for a constant. It is doubtful that most C compilers would recognize these values as constants and propagate them accordingly. The objective is to remove assignments of constants into the descriptor table and replace references to those descriptor locations with constant values.

### **25.1.3 Variable Initialization**

At the beginning of every intermediate procedure there are several loops that initialize local variables and parameters. Sometimes these loops initialize only one or two variables. In certain situations the loop will not be executed at all, but the code for the loop is still generated, requiring a comparison when the program executes. The object of this part is to simplify the initialization loops and to remove loops that have no effect.

## **25.2 Enabling Optimizations**

All the changes made to the Icon compiler in order to implement these optimizations were done with C compiler directives so that each optimization can be turned on or off during compilation.

All directives are included in `src/c/define.h`. The symbols `OptimizePoll`, `OptimizeLit`, and `OptimizeLoop` turn on redundant `Poll()` removal, literal propagation, and loop optimizations respectively.

An additional symbol, `LoopThreshold` has a default value of 7. This constant, used in the loop unrolling optimizations, is a limit on the number of entries that may be unrolled in variable initialization loops.

## **25.3 Intermediate Code Representation**

This section briefly describes how the intermediate C code is represented and generated internally by the Icon compiler. The majority of the functions that generate this internal representation and

print it to a file are contained in the following compiler source files: `ccode.c`, `codegen.c`, and `inline.c`.

### 25.3.1 How Code is Generated

Once the source code is parsed and evaluated, the intermediate C code needs to be generated and output to a file for compilation by the native C compiler. First the compiler builds a syntax tree plus symbol tables and other necessary structures. Then, the header file is created. This includes standard definitions necessary for all Icon programs and structures and variables specific to the program being compiled. Next, the `proccode` function is called for each function in the tree. This outputs the function definition and variable in initialization code, and then steps through the syntax tree and creates C code to represent the body of the function. After all the code for the body of the current procedure is generated internally, the code is then written to the file.

The internal C code is represented through a C structure called `struct code` which is shown below.

```
struct code {
    int cd_id;
    struct code *next;
    struct code *prev;
    union cd_fld fld[1];
};
```

The `cd_id` field is an identifier signaling what type of code is held in this structure. This field may be set to one of the following enumerated values. Each value corresponds to a type of code that can be written to the intermediate C code. The table in Figure 25-1 contains the enumerated name along with its integer value and a short description.

<i>Code Type</i>	<i>Value</i>	<i>Description</i>
C_Null	0	No code in this struct
C_CallSig	1	Call a signal (function)
C_RetSig	2	Return a signal

<i>Code Type</i>	<i>Value</i>	<i>Description</i>
C_NamedVar	3	Reference a variable
C_Goto	4	Goto statement
C_Label	5	Label statement
C_Lit	6	Literal value
C_Resume	7	Resume signal
C_Continue	8	Continue signal
C_FallThru	9	Fall through signal
C_PFail	10	Procedure failure
C_PRet	11	Procedure return
C_PSusp	12	Procedure suspend
C_Break	13	Break out of signal handling switch
C_LBrack	14	Start of a new C block
C_RBrack	15	End of a C block
C_Create	16	Call create() for a create expression
C_If	17	If statement
C_SrcLoc	18	Source file name
C_CdAry	19	Array of code pieces

Figure 25-1: Code Types

The fld field is important and is directly linked to what type of code the struct code is defined as. For example, if a struct code is defined as C\_If then fld[0] is a pointer to another struct code that corresponds to the if portion of the statement, and fld[1] is another pointer to a struct code representing the then portion of the statement. In fact there are two macros for extracting each pointer. These macros plus macros for all the other code types are found in the ccode.h header file. However, there is one special case that requires some explanation. If the cd\_id is C\_CdAry then the fld element is an unspecified length of cd\_fld unions. In this case all even indices into the array are tags describing the contents of the following array element. There is a special marker, A\_End, that signifies the end of the array.

Figure 25-2 shows these field identifiers along with their corresponding fields for an assignment statement.

Figure 25-2: Fields and Their Values in an Assignment

It is important to note that only when the `cd_id` is `C_CdAry` will the field identifiers be present. Figure 25-3 gives the possible values for these tags.

<i>Element Type</i>	<i>Value</i>	<i>Description</i>
<code>A_Str</code>	0	Pointer to a string
<code>A_ValLoc</code>	1	Pointer to a struct <code>val_loc</code>
<code>A_Intgr</code>	2	Integer value
<code>A_ProcCont</code>	3	Procedure continuation
<code>A_SBuf</code>	4	String buffer
<code>A_CBuf</code>	5	Cset buffer
<code>A_Ary</code>	6	Pointer to a subarray of struct code structures

<i>Element Type</i>	<i>Value</i>	<i>Description</i>
A_End	7	Marker for end of array

Figure 25-3: Element Types

For the most part the C\_CdAry is used for miscellaneous code that is not covered by the other 19 code types. Most simple assignments fall into this category. The last two elements of a struct code, next and prev, are links to the next and previous struct code structures in the chain.

## 25.4 Redundant Function Calls

An example of this type of optimization are several function calls needed to handle certain run-time system activities in Icon that are included in the generated C code. For example, throughout the code Icon places a call to the macro Poll() which checks for pending events such as window redraws. In some cases there is a call to Poll() followed by an assignment and another call to Poll() which is far too frequent. The placement of these calls can be analyzed to determine when they are necessary.

The solution to this problem entails analyzing where the calls to Poll() were being placed. The Poll() macro is inserted into the generated code by the function setloc which is located in the file ccode.c of the compiler source. The old method for determining when to insert a call to this function is somewhat confusing. Also setloc does more than insert these function calls so there was no change in the way it determined when to put a call in. Instead, a call to analyze\_poll is made that determines if it is safe to remove the previous occurrence of the Poll function. To accomplish this, a global variable is kept, called lastpoll, which is a pointer of type struct code, and it is always assigned to the location of the last Poll function. Of course, initially lastpoll is NULL. The global variable is declared in ccode.c. The prototypes for the two new functions are as follows:

```
int analyze_poll(void)
```

This function analyzes the code between the last occurrence of the Poll() macro and the current position. If there are no function calls (C\_CallSig), return signals (C\_RetSig), C code blocks (C\_LBrack or C\_RBrack), return calls (C\_PRet), procedure suspends (C\_PSusp), or break (C\_Break), then the previous instance of Poll will be removed; otherwise, it will be left in place.

The reason why the above code types are restricted is because they all involve calling other functions. If it were known that these functions were short and did not call other functions, then the call to Poll() could be removed without worry; however, this kind of detailed analysis is not performed and is inhibited by the fact that some of these functions represented by C\_CallSig may be library functions and these are linked at C compile time.

Also, regardless of whether the previous instance of a call to Poll() is removed the new call to Poll() is added to the code list and the lastpoll variable is updated.

```
novalue remove_poll(void)
```

This function actually removes the call to `Poll()` by setting the `cd_id` field in the struct code structure to `C_Null`. It is important to note that the struct code that represents the call to `Poll()` is not physically deallocated from the list. Its `cd_id` field is simply set to `C_Null` because removing it introduces side effects which are either errors during C compilation or the misplacement of `goto` labels which affects the flow of execution and unpredictable results. This occurs because a struct code of type `C_Goto` may reference the removed node.

## 25.5 Icon Literals and Constant Propagation

Constant propagation was the second most difficult optimization to implement next to the new type representation because the Icon compiler generates a complex data structure that contains Icon values, including literals. These Icon literals are assigned into this tended descriptor table even though these values are constants. There are several reasons to improve the representation of these constants.

First, by changing these complicated Icon literals to simple C literals, the resulting executable code will be smaller. Secondly, there is the issue of constant propagation. In many cases, an index into the descriptor table is passed to a function or assigned to a variable. The question that arises is whether the C compiler can detect that the descriptor table value being passed is a constant that can be propagated to all places where the descriptor table is used. For example, the following code fragment is fairly common:

```
r_frame.tend.d[4].dword = D_Integer;
r_frame.tend.d[4].vword.integr = 1;
irslt = sub(argp[0].vword.integr, r_frame.tend.d[4].vword.integr);
```

In this section of code, the structure `r_frame.tend.d[4].vword.integr` is assigned a value and then immediately used. This code can be simplified to:

```
irslt = sub(argp[0].vword.integr, 1);
```

Note that the assignment of the literal into the descriptor table may no longer be necessary; time savings on this initialization may be as great as the savings for the simplified reference.

### 25.5.1 Tended Descriptor Tables

Most functions contain a tended descriptor table. This is an array of descriptor structures which contain either an integer, pointer to a string, pointer to a block, or a pointer to another descriptor location. A named variable is assigned a specific index into the descriptor table while temporary variables are assigned an index, but other temporary variables can be assigned into the same cell

many times over. Named variables are all those that are explicitly used in the Icon source code such as loop control variables, and temporary variables are constants values (regardless of type). For example, in the first Icon code example the value 2.4 is assigned its own location into the descriptor table. The same thing holds true for the second example. The string "foo" is assigned its own location. Because both these values are only literals in the Icon code, they are given temporary locations in the tended descriptor table that may be used over again.

```

if (x_val = 2.4) then
    do_something(x_val)
...
...
if (str_val == "foo") then
    do_something(str_val)

```

For example, if the constant 2.4 is not used after the second code fragment then "foo" may be assigned into the location previously occupied by 2.4.

### 25.5.2 Analyzing Literal Assignments

Several new functions were introduced in order to analyze all constants and their use. Inside the function proccode before the internal C code is written to a file, a call to `analyze_literals` and `propagate_literals` is made which does the propagation. The `analyze_literals` function builds a table which contains information such as the scope of a descriptor entry, whether it is safe to propagate a literal, and the literal value. The table structure is given below.

```

struct lit_tbl {
    int    modified;
    int    index;
    int    safe;
    struct code *initial;
    struct code *end;
    struct val_loc *vloc;
    struct centry *csym;
    struct lit_tbl *prev;
    struct lit_tbl *next;
};

```

The field `modified` is a flag which can be set to one of the enumerated types in Figure 25-4.

<i>Name</i>	<i>Value</i>	<i>Description</i>
NO_LIMIT	0	Descriptor never changes
LIMITED	1	Descriptor value does change, propagate any type
LIMITED_TO_INT	2	Descriptor value does change, propagate only if integer
NO_TOUCH	3	Descriptor value should not be propagated

Figure 25-4: Modify Flags

The NO\_LIMIT value refers to those descriptor locations that always contain the same constant. That is, no other value shares the same descriptor location, and it may be propagated freely without conflicts. The LIMITED value refers to those descriptor locations that are either reused at some point or are modified in some way. The value LIMITED\_TO\_INT is similar except that special care must be taken when propagating this constant. For example, a constant such as a string should not be propagated everywhere an integer may be propagated.

Lastly, the value NO\_TOUCH refers to descriptor locations that should not be propagated. These descriptor locations often contain loop control variables which are marked as temporary but should under no circumstances be replaced with their initial values. For example, the first code fragment shows unoptimized code, and the second fragment is the same code but with constants propagated. Descriptor location 6 should not be touched because it serves as a loop control variable while the use of location 7 may be replaced with its constant value 10 even though the same location is assigned a new value later on after label L9.

```

    r_frame.tend.d[6].dword = D_Integer;
    r_frame.tend.d[6].vword.integr = 1;
    r_frame.tend.d[7].dword = D_Integer;
    r_frame.tend.d[7].vword.integr = 10;
L8:
    if (!(r_frame.tend.d[6].vword.integr <=
        r_frame.tend.d[7].vword.integr) )
        goto L9;
    ...
    ++r_frame.tend.d[6].vword.integr;
    goto L8;
L9:
    r_frame.tend.d[7].dword = D_Integer;
    r_frame.tend.d[7].vword.integr = 7;

```

---

```

    r_frame.tend.d[6].dword = D_Integer;
    r_frame.tend.d[6].vword.integr = 1;

```

```

L8:
    if (!(r_frame.tend.d[6].vword.integr <= 10) )
        goto L9;
    ...
    ++r_frame.tend.d[6].vword.integr;
    goto L8;
L9:
    r_frame.tend.d[7].dword = D_Integer;
    r_frame.tend.d[7].vword.integr = 7;

```

The field `index` is the index into the descriptor table for each constant.

The field `safe` refers to whether or not it is safe to modify the end field. This field refers to the point in the intermediate code beyond which it is no longer safe to propagate this value. The end field is sometimes modified when inserting a new entry into the literal table. This is described in detail under the `tbl_add` function presented shortly.

The fields `initial` and `end` refer to the scope where it is safe to propagate the current literal between. If `end` is `NULL` then it is safe to propagate to the end of the function.

The fields `vloc` and `csym` are pointers to either a struct `val_loc` or a struct `centry` which contain the constant value of the current descriptor. The struct `centry` member points to the corresponding location in the global symbol table of constant values maintained by the Icon compiler.

The fields `prev` and `next` are necessary to make the table doubly linked.

Also, it should be noted that the number of entries in the literal table is fairly small. During compilation of *Ctree*, the largest literal table used contained 15 entries.

The analysis phase consists of stepping through the struct code chain for each function looking for each instance of a literal. Figure 25-5 shows how a literal is contained within a struct code structure. At this point, a new entry into the literal table is created that keeps track of where in the code the literal is assigned into the descriptor table and a pointer to the struct `centry` structure where the literal value is kept. This phase also attempts to find the point at which descriptor entries are assigned new values. Thus a scope is defined which the constant may only be propagated between.

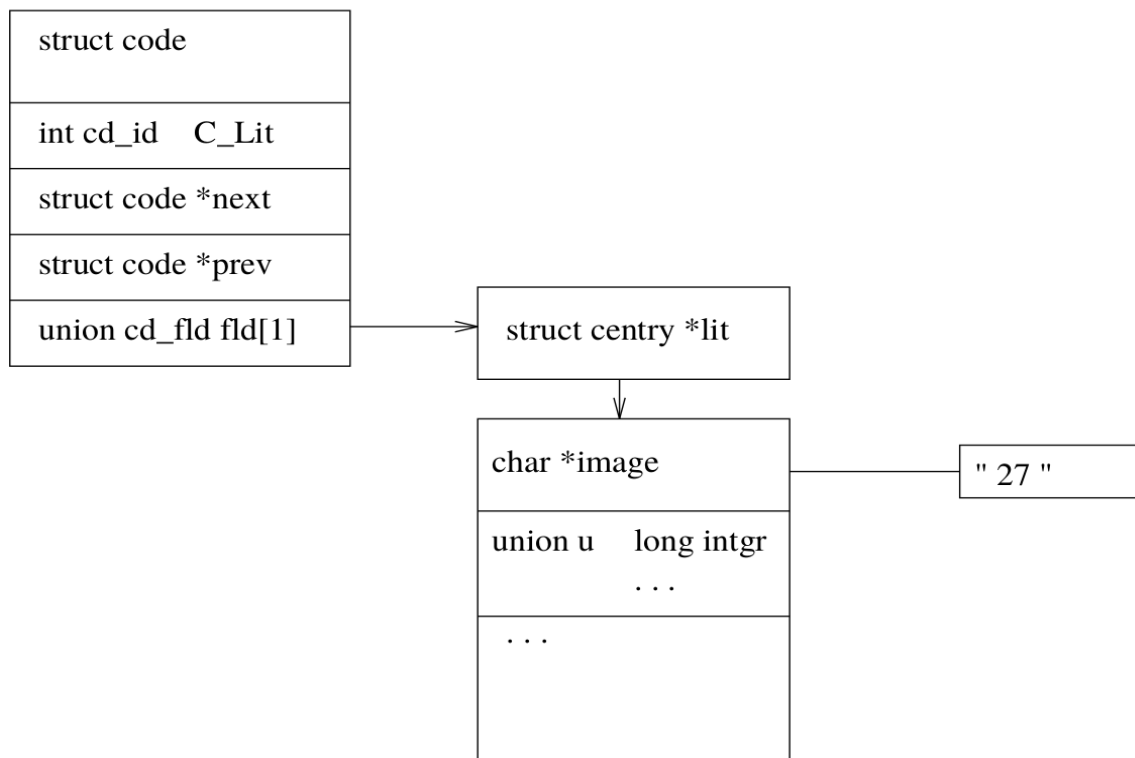

Figure 25-5: Literal

Once the analysis is complete and the literal table is built then the function `propagate_literals` is called which goes through each entry in the literal table and examines the code beginning at the initial field until the struct code referenced by the end field is encountered. If a struct code is found that references the descriptor containing the current literal then that reference is replaced by the literal itself. Figure 25-2 showed a fragment of code for generating an assignment, and Figure 25-6 shows the same fragment with the second descriptor replaced with its literal (assuming that descriptor location 8 was previously initialized to 27). It is important to note that only the struct `val_loc` on the right side of the equal sign will be replaced by its literal.

Figure 25-6: After Assignment

### 25.5.3 New Functions

The following functions were created to support the constant propagation optimization. All these functions are placed in the compiler source file `ccode.c`. Each function used in the constant propagation is prototyped and described below.

```
struct lit_tbl *alc_tbl(void)
```

This function allocates a `struct lit_tbl` entry that contains information about a literal and its usage. It first checks a global pointer called `free_lit_tbl` to see if there are any free table structures that may be reused. If there are no free structures in this list then a new structure is allocated. Lastly, the fields are initialized to predefined values.

```
novalue free_tbl(void)
```

This function frees the memory used for the current table by attaching the current table to the list of free table structures (`free_lit_tbl`).

```
novalue tbl_add(struct lit_tbl *add)
```

This function adds a new `struct lit_tbl` structure into the current table. The insertion is to the end of the table plus it checks for the previous use of the descriptor location used in the element being added. For the previous use of the same element, that location's end pointer is set to the initial pointer of the element being added. In essence, this defines a scope for each descriptor location. Once end is set for the first time, it should not be changed later.

```
int substr(const char *str, const char *sub)
```

This function is used to scan strings for logical operators (==, !=, >=, <=, etc). If the string represented by sub is found in str then TRUE is returned. It is necessary to identify these operators so a string is not propagated as an operand to one of these operators which is not valid C syntax.

```
int instr(const char *str, int chr)
```

This function is used to determine if a string contains an assignment operator. This function will return TRUE if the string str contains any type of assignment (=, +=, -=, \*=, /=, or %=).

```
novalue invalidate(struct val_loc *v, struct code *end, int code)
```

This function sets values for an element in the literal table. For all literal table entries that point to the struct val\_loc represented by v the end field is set to end with the modified field set to code. code can be one of the following enumerated values: NO\_LIMIT, LIMITED, LIMITED\_TO\_INT, or NO\_TOUCH.

```
novalue analyze_literals(struct code *start, struct code *top, int lvl)
```

This function steps through the struct code list for each function, building up a literal table, and analyzing the scope between which each literal can be safely propagated. It checks for loop control variables, when and if the value of a constant descriptor location changes, and checks to see if a descriptor location is passed by reference to any functions.

```
novalue propagate_literals(void)
```

This function steps through each entry in the literal table and begins to replace occurrences of the descriptor location with the literal between the struct code structures from the initial field to the end field. The function eval\_code is called to do the actual propagation.

```
int eval_code(struct code *cd, struct lit_tbl *cur)
```

This function first checks to see if the descriptor index of the code currently being examined matches that of the current literal table entry. If the current descriptor is accessed as an integer or a string then the descriptor is replaced with the literal value. Also, the modified is checked to see if there are any restrictions on replacement. The table in Figure 25-7 lists the restrictions for each possible value of modified.

<i>Name</i>	<i>Replacement Restrictions</i>
NO_LIMIT	Always replace

<i>Name</i>	<i>Replacement Restrictions</i>
LIMITED	Always replace within initial and end
LIMITED_TO_INT	Only replace if used as int, also limited by scope
NO_TOUCH	Never replace

Figure 25-7: Replacement Policy

The actual replacement of a descriptor reference to a literal is accomplished by setting the current index into the fld array to the A\_Str type and allocating a string where the literal is copied into. Figure 25-2 and Figure 25-6 illustrate an occurrence of this.

## 25.6 Variable Initialization

Another issue is the initialization of the descriptor tables in each C function that is generated by the Icon compiler. Many of the generated functions contain a loop that initializes all the entries of the local descriptor table to the null descriptor. This is rather cumbersome and generates a great deal of overhead.

### 25.6.1 Eliminating Dead Code

The first optimization to the variable initialization was to eliminate “dead” code, which is code that is never executed. In some cases the loops that initialize the descriptor tables resembled this:

```
for (i = 0; i < 0; ++i)
    r_frame.tend.d[i] = nulldesc;
```

This code is generated for Icon library functions in the function `outerfnc` located in `codegen.c`. There is a separate function that outputs similar code for user written functions which does check to see if the loop will ever execute. Both functions contain a variable `ntend` which hold the number of descriptor entries. A simple check for equality with zero was added.

### 25.6.2 Loop Unrolling

Every user function initializes all tended descriptor entries to the value of the null descriptor `nulldesc` at the beginning of the function. It is a simple one-line for loop similar to the following code fragment.

```

for (i = 0; i < 3; ++i)
    r_frame.tend.d[i] = nulldesc;

```

Also, upon examining the C code generated from several programs, the number of descriptor entries per procedure rarely exceeds ten. Because this is a relatively small number, these loops can be unrolled into a series of assignments, and the loop may be removed. The following code is the above loop unrolled.

```

r_frame.tend.d[0] = nulldesc;
r_frame.tend.d[1] = nulldesc;
r_frame.tend.d[2] = nulldesc;

```

While this will increase the size of the generated code, the loop overhead is eliminated. There is a limit placed on the number of loop iterations that will be unrolled which is defined in `define.h`. Currently, this value, `LoopThreshold`, is set to 6. Because this number and the number of descriptor table entries is small, the number of unrolled elements is reasonable, and the code size is not greatly affected.

The code that unrolls these loops is in the function `outerfnc` in the file `codegen.c`. Because this change is only several lines, the code that implements loop unrolling is included below.

```

#ifdef OptimizeLoop
    if (ntend > 0) /* Check for dead code */
        for (i=0; i < ntend ;i++)
            fprintf(codefile,
                " r_frame.tend.d[%d] = nulldesc; \n",i);
#else
    fprintf(codefile, "for (i=0; i < %d ;i++) \n", ntend);
    fprintf(codefile, " f_frame.tend.d[i] = nulldesc;\n");
#endif

```

## 25.7 Results

Several tests were run to determine whether the code generation optimizations were effective. These optimizations were performed in hopes of improving the execution speed of the compiled program, reducing the size of the intermediate code and the resulting executable, and the compilation time.

Overall, the optimizations improved the execution speed by a modest amount. The improvement is roughly between 6-8.25%. While this is not as great as was hoped, it still is an improvement. The code size of both the intermediate code and the generated executable are surprisingly smaller. The loop unrolling seemed to be offset by the constant propagation which eliminated unnecessary assignments and references. The size of the executables were reduced by approximately 4-8% for large programs, but there was no change in executable size for small programs (20 lines). The size of the generated C file was consistently around 3% smaller than before the optimizations. Also, on average around half of all calls to `Poll()` were removed, and in one case, two thirds were eliminated.

The rest of this section presents detailed information on the results of the optimizations for removing redundant function calls, unrolling loops, removing dead code, and propagating literals. Details of the results of the code generation optimizations are presented in the areas of execution speed, code size, and compilation time. These tests were run on several programs. The first program, *Beards*, generates production grammars, non-terminals, terminals, and epsilon sets from an input grammar. The second program, *Yhcheng*, is a line editor similar to `ed` which also has revision control capabilities. For the code size and compilation time tests, two other programs, *Ctree* and *Sphere*, were used for tests. *Beards*, *Yhcheng*, and *Ctree* are all large programs while *Sphere* is included because it is a very small program (less than 25 lines). All timings performed used the Unix or Linux time utility. Also note that these timings were performed with all optimizations turned on including the type representation optimization.

### 25.7.1 Execution Speed

Each program was run 10 times with sample input and averages were computed. Figure 25-8 summarizes the execution times for *Beards* and *Yhcheng*.

<i>Program</i>	<i>Version</i>	<i>User</i>	<i>System</i>	<i>Elapsed</i>
	Optimized	0.5	0.12	00:01.17
Beards	Unoptimized	0.52	0.13	00:01.27
	Improvement	4.97%	9.09%	8.25%
	Optimized	0.59	1.11	00:01.99
Yhcheng	Unoptimized	0.62	1.27	00:02.14

<i>Program</i>	<i>Version</i>	<i>User</i>	<i>System</i>	<i>Elapsed</i>
	Improvement	4.21%	12.91%	6.79%

Figure 25-8: Execution Times

### 25.7.2 Code Size

Tests were run on the same two programs to determine if there was an improvement in either the intermediate code size or the size of the resulting executable. Figure 25-9 displays the code sizes for *Beards*, *Yhcheng*, *Ctree*, and *Sphere*. The first three programs are large (500-1800 lines) while *Sphere* is small (20 lines).

<i>Program</i>	<i>Version</i>	<i>C File</i>	<i>H File</i>	<i>Executable</i>
	Optimized	246159	12967	204800
Beards	Unoptimized	252041	12967	212992
	Improvement	2.33%	0.00%	3.85%
	Optimized	554014	46168	294912
Yhcheng	Unoptimized	568118	46168	319488
	Improvement	2.48%	0.00%	7.70%
	Optimized	290536	61545	225280
Ctree	Unoptimized	298813	61545	237568
	Improvement	2.77%	0.00%	5.17%
	Optimized	82289	49755	159744
Sphere	Unoptimized	84972	49755	159744
	Improvement	3.16%	0.00%	0.00%

Figure 25-9: Code Sizes

Much of the reduction in code size can be attributed to the removal of redundant calls to *Poll*, and it is this reduction that offsets the loop unrolling. Improvements on *Beards*, *Yhcheng*, and *Sphere* show that almost one half of all calls to *Poll* were eliminated; however, *Ctree* shows almost a two thirds reduction. Figure 25-10 shows the number of calls to *Poll* for each program before and after the optimization.

<i>Test Program</i>	No. Before	No. After
Beards	810	481
Yhcheng	2144	1135
Ctree	745	293
Sphere	40	22

Figure 25-10: Number of Redundant Functions Removed

### Compilation Time

Lastly, the compilation times for the sample programs are given. Each program was compiled five times with the results averaged. Again, results for the *Beards*, *Yhcheng*, *Ctree*, and *Sphere* are in Figure 25-11.

<i>Program</i>	<i>Version</i>	<i>User</i>	<i>System</i>	<i>Elapsed</i>
	Optimized	43.57	1.77	00:47.40
Beards	Unoptimized	60.93	1.65	01:02.93
	Improvement	28.49%	-7.27%	24.68%
	Optimized	116.97	2.76	02:04.14
Yhcheng	Unoptimized	163.37	2.86	02:49.71
	Improvement	28.40%	3.50%	26.85%
	Optimized	65.26	2.54	01:13.44
Ctree	Unoptimized	92.25	2.88	01:47.44
	Improvement	29.26%	11.81%	31.65%
	Optimized	11.98	1.83	00:16.36
Sphere	Unoptimized	13.62	2.22	00:18.85
	Improvement	12.04%	17.57%	13.21%

Figure 25-11: Compile Times

### 25.7.3 Analysis of Intermediate Code Optimizations

The gains in execution speed and code size were modest but not startling. For the most part, improvement was less than 10%. However, the results for compilation time are more promising. The speedup was between 24% and 31% for large programs, which is between a 15 and 45 second improvement.

The eliminated functions calls most likely have a negligible effect on execution speed but greatly contributed to the reduction in code size. For example, on a large program like *Yhcheng* which contained more than 18,600 lines of C code, approximately 450 redundant calls were removed. It was not expected that eliminating “dead” initialization loop would have much effect on execution speed. Constant propagation and loop unrolling probably accounted for the improved execution times. However, more of an improvement was expected from the constant propagation optimization. Two possible explanations could be that the native C compiler is able to reduce the complex structure lookup to its literal value or that the compiler has so much other baggage slowing down execution that the constant propagation improvement was not enough to make a great difference. The second explanation seems more likely.

The size of the intermediate code and executable code were also modestly improved. The elimination of redundant function calls offset the addition of code due to loop unrolling. Also, eliminating unnecessary initializations for literals that were propagated contributed to the smaller code sizes. It is important to note that as it is, the compiler generates an enormous amount of code for procedure continuations and suspensions so that 25-30% of the intermediate code are these functions and the rest is user code.

Lastly, the speed of compilation was a pleasant surprise; however, I do believe that this improvement is due to the type inferencing optimization because the current optimizations being discussed only add extra logic to improve the generated code. Another significant factor is that less memory is being used by the type inferencing system, which therefore causes less access to virtual memory. I should note that all the tests were run with that optimization on, and the improvement to type inferencing simplifies the type system in many ways. To determine if a specific bit is set, the old system had to create a mask and find the appropriate index into a long bit vector. The new system requires a single comparison in the case of the five builtin types.

## 25.8 Conclusion and Future Optimizations

All of the optimizations discussed in this chapter have been implemented. Some of the optimizations performed extremely well while others did not have much effect. The type representation change provided a substantial improvement on the memory usage required by the type inferencing system. As was stated early, the compiler still uses too much memory to be of much use to the average Icon programmer but is much better suited to offering the added speedup of compiled code when occasionally necessary.

The intermediate code optimizations were really just the tip of the iceberg of all the possible improvements to this area. The removal of redundant calls to system calls was a small improvement. Literal propagation was probably the most significant improvement along with loop unrolling. Further optimizations in this area are likely to yield the best improvements to performance.

After studying the generated code, several other optimizations were identified that may offer

additional improvements to both the speed of execution and the size of the intermediate and executable code. The next few paragraphs describe additional optimizations and are organized in the order of the easiest to hardest to implement.

1. For the unrolled descriptor initializations change the indexing array to pointer arithmetic which is faster. For example the following code fragment is modified as follows:

```
r_frame.tend.d[0] = nulldesc;
r_frame.tend.d[1] = nulldesc;
r_frame.tend.d[2] = nulldesc;
```

---

```
register dptr p;
p = r_frame.tend.d;
(p++)->dword = nulldesc;
(p++)->dword = nulldesc;
```

1. Analyze the logic of loops and also unroll smaller ones. For example, the following loop appears at the beginning of most functions.

```
for (i = 0; i < r_nargs ; ++i)
    deref(&r_args[i], &r_frame.tend.d[i + 0]);
for(i = r_nargs; i < 2 ; ++i)
    r_frame.tend.d[i + 0] = nulldesc;
```

In this case `r_nargs` cannot be greater than two because it was earlier declared to have only two entries. It would be necessary to guarantee that `r_nargs` can never be more than two, but if it is certain that there are exactly two elements then we can write the initialization loop as follows:

```

if(r_nargs > 0) {
    deref(&r_args[0], &r_frame.tend.d[0]);
    if (r_nargs > 1)
        deref(&r_args[1], &r_frame.tend.d[1]);
    else
        tend.d[1].dword = D_Null;
}
else
    tend.d[0].dword = D_Null;

```

This optimization could lead to a gain in execution speed. For example, if the unrolling is performed on descriptors with array sizes of one or two, approximately 40% of these loops would be unrolled.

1. An easy and obvious solution would be to simplify expressions like `i + 0` which commonly occur. This will not improve execution time because the C compiler will catch this, but by removing it before writing the statement to the intermediate file, the compile time of the C compiler will be improved.
2. Another easy optimization would be to shorten variable names. This causes a penalty by having to write long names such as `r_frame.tend.d` to file and then having the C compiler read it back in. This could be changed to `r_f.t.d`. While this makes the intermediate C code hard to read, the intermediate code is not meant to be inspected by the user and will result in faster compilations.
3. For the initialization loops present in all functions, remove the initialization of the loop control variable when unnecessary. Consider the following loop:

```

for (i = 0; i < r_nargs ; ++i)
    deref(&r_args[i], &r_frame.tend.d[i + 0]);
for(i = r_nargs; i < 2 ; ++i)
    r_frame.tend.d[i + 0] = nulldesc;

```

The variable `i` in the second loop does not need to be initialized since it is already at the value that it is supposed to be for the second loop. The next fragment of code illustrates this change.

```

for (i = 0; i < r_nargs ; ++i)
    deref(&r_args[i], &r_frame.tend.d[i + 0]);
for( ; i < 2 ; ++i)
    r_frame.tend.d[i + 0] = nulldesc;

```

While this change is very easy, it is questionable whether this will provide noticeable improvement in execution except in large programs where these loops are very common.

1. Assignments of the `r_frame.tend.d` structures may be simplified. Consider the following assignment:

```

r_frame.tend.d[2] /* i */.vword.integr =
    r_frame.tend.d[4].vword.integr;
r_frame.tend.d[2] /* i */.dword = D_Integer;

```

This could be changed into a single assignment as follows:

```

r_frame.tend.d[2] = r_frame.tend.d[4];

```

This optimization would require more work than the previously described ones. Each `struct val_loc` structure would have to be examined, including the context in which it is used in order to catch assignments such as this; however, these assignments are very common and could lead to substantial gains in execution speed.

1. Similarly, perform the same simplified descriptor assignment on global descriptor locations. A method needs to be created for changing global assignments such as:

```

globals[63] /* rnode */.dword = D_Integer;
globals[63] /* rnode */.vword.integr = 1;

```

into

```

globals[63] /* rnode */ = onedesc;

```

where `onedesc` is a single descriptor that already contains the values of the `dword` and `vword` being assigned. This could be performed by creating several constant descriptors for the common values such as 0 or 1. Like the previous optimization, this change will offer a smaller improvement to execution speed because global descriptor assignments occur much less frequently.

1. When a variable is dereferenced, it is often the case that the variable location is passed in for both parameters to the `deref` function. For example, in the following code example, `r_frame.tend.d[7]` is the variable being dereferenced and the location where the dereferenced value is to be placed. This can be simplified by creating another version of `deref`, perhaps named `deref1`, that takes a single argument, dereferences it, and places the dereferenced value into the parameter location.

```
deref(&r_frame.tend.d[7], &r_frame.tend.d[7]);
```

1. Another issue is redundant constant initializations. Consider the following code:

```
r_frame.tend.d[8].dword = D_Integer;
r_frame.tend.d[8].vword.integr = 1;
if (!(argp[1] /* level */.vword.integr == 1) )
    goto L19 /* bound */;
r_frame.tend.d[8].dword = D_Integer;
r_frame.tend.d[8].vword.integr = 1;
```

The descriptor location 8 is assigned the value of 1 and then a conditional statement is performed which is followed by a possible `goto`. If the jump does not occur then the same descriptor location is assigned the same value over again. Clearly the second assignment is wasteful and needs to be eliminated. This would require fairly aggressive analysis of the intermediate code in order to catch these code sequences, but does offer the benefits of increased execution speed and smaller code size.

A more difficult optimization that offers a substantial reduction in the size of the intermediate and executable code deals with the initialization functions that set up frames. In the case of *Ctree*, over 30% of the generated C code consists of these functions. For example, in *Ctree* there are two functions named `P06i_set_value_Vtext` and `P03n_unset_Vbool_coupler` which are identical except for their frame structures, similarly defined as `PF06i_set_value_Vtext` and `PF03n_unset_Vbool_coupler`; however, these structures are identical. A possible solution would be to write out one copy of each unique frame structure along with its corresponding function that would initialize that frame. In addition to the reduction of code size this would result in faster compilations and faster loading of the resulting executable. This last optimization is the most difficult and would require extensive changes; however, this optimization offers the best improvements in code size, execution time, and compile time.

# Chapter 26

## Future Work on the Compiler

### 26.1 Summary of Part II

The underlying ideas used in type inferencing, liveness analysis, and temporary variable allocation were explored using prototype systems before work was started on the compiler described in this part of the compendium. The fundamental reasons for creating the compiler were to prove that these ideas could be incorporated into a complete and practical compiler for Icon, to explore optimizations that are possible using the information from type inferencing, and to determine how well those optimizations perform. The goal of proving the usefulness of ideas continues a long tradition in the Icon language project and in the SNOBOL language project before it.

The prototype type inferencing system demonstrates that a naive implementation uses too much memory; implementation techniques were developed for the compiler to greatly reduce this memory usage. As the design and implementation of the compiler progressed, other problems presented themselves, both large and small, and solutions were developed to solve them. These problems include how to elegantly produce code either with or without type checking, how to generate good code for simple assignments (a very important kind of expression in most Icon programs), how to generate code that uses the continuation-passing techniques chosen for the compilation model, and how to perform peephole optimizations in the presence of success continuations.

This part of the compendium describes the problems addressed by the Icon compiler and why they are important to the compiler, along with innovative solutions. It presents a complete set of techniques used to implement the optimizing compiler. Performance measurements demonstrate the improvements brought about by the various optimizations. They also demonstrate that, for most programs, compiled code runs much faster than interpreted code. Previous work has shown that simply eliminating the interpreter loop is not enough to produce large performance improvements [tr88-31.]. Therefore, the measurements show that the set of techniques, in addition to being complete, is also effective.

## 26.2 Future Work

The Icon compiler builds upon and adds to a large body of work done previously by the Icon project. There are many problems and ideas relating to the implementation of Icon that remain to be explored in the future. Several are presented in earlier chapters. Others are described in the following list.

- The quality of type inferencing can be improved. For example, if

$x \parallel y$

is successfully executed, both  $x$  and  $y$  must contain lists. The current version of type inferencing in the compiler does not use this information; it updates the store based on result types and side effects, but not based on the argument types that must exist for successful execution without run-time error termination. Another improvement is to extend the type system to include constants and thereby perform constant propagation automatically as part of type inferencing. The type system can also be extended to distinguish between values created in allocated storage and those that are constant and do not reside in allocated storage. A descriptor that never contains values from allocated storage does not need to be reachable by garbage collection.

- In spite of large improvements in the storage requirements of type inferencing over the prototype system, type inferencing still requires large amounts of memory for some programs. A suggestion by John Kececioglu [johnk.] is to explore the use of applicative data structures that share structure with their predecessors. The space required by type inferencing has largely been solved by Anthony Jones and Mike Wilder. Wilder's hash tables of copy-on-write type vectors can be viewed as a realization of Kececioglu's suggestion.
- Type inferencing provides information about values that do not need run-time type information associated with them. In the case of integers and reals, this information along with information from the data base about run-time operations can be used to perform computations on pure C values and to demote Icon descriptor variables to simple C integer and double variables. The current compiler makes little use of these opportunities for optimization. Numerous other optimizations using the information from type inferencing are possible beyond what is currently being done. One of them is to choose the representation of a data structure based on how the data structure is used.
- Translating constant expressions involving integer and real values into the corresponding C expressions would allow the C compiler to perform constant folding on them. For other Icon types, constant folding must be performed by the Icon compiler. This is particularly important for csets, but is not presently being done.

- O'Bagy's prototype compiler performs two kinds of control flow optimizations. It eliminates unnecessary bounding and demotes generators that can not be resumed. The code generation techniques used in this compiler combined with the peephole optimizer automatically eliminate unnecessary bounding. The peephole optimizer also automatically demotes generators that are placed in-line. Enhancements to the peephole optimizer could effect the demotion of generators that are not placed in-line.
- The compiler uses a simple heuristic to decide when to use the in-line version of an operation and when to call the function implementing the operation using the standard calling conventions. More sophisticated heuristics should be explored.
- Temporary variables can retain pointers into allocated storage beyond the time that those pointers are needed. This reduces the effectiveness of garbage collection. Because garbage collection does not know which temporary variables are active and which are not, it retains all values pointed to by temporary variables. This problem can be solved by assigning the null value to temporary variables that are no longer active. However, this incurs significant overhead. The trade off between assigning null values and the reduced effectiveness of garbage collection should be explored.
- The Icon compiler generates C code. If it generated assembly language code, it could make use of machine registers for state variables, such as the procedure frame pointer, and for holding intermediate results. This should result in a significant improvement in performance (at the cost of a less portable compiler and one that must deal with low-level details of code generation).
- Several of the analyses in the compiler rely on having the entire Icon program available. Separate compilation is very useful, but raises problems. One possible solution is to change the analyses to account for incomplete information. They could assume that undeclared variables can be either local or global and possibly initialized to a built-in function or unknown procedures, and that calls to unknown operations can fail, or return or suspend any value and perform any side-effect on any globally accessible variable. This would significantly reduce the effectiveness of some analyses. Another approach is to do incremental analyses, storing partial or tentative results in a data base. This is a much harder approach, but can produce results as good as compiling the program at one time.
- Enhancements to the compiler can be complemented with improvements to the run-time system. One area that can use further exploration is storage management.

## **Part III**

# **The Implementation of Unicon**

by Clinton L. Jeffery, Michael D. Wilder, and Jafar Al Gharaibeh

# Chapter 27

## The Unicon Translator

Unicon was originally a modest addition to Icon. As much as possible, features are implemented by extending existing functions with new semantics, and by the addition of new functions and keywords with no new syntax. Originally, the object-oriented facilities were implemented as a simple line-oriented preprocessor named Idol. When Idol was merged with the Posix and ODBC facilities to become Unicon, the Idol preprocessor was substantially modified to a full parser that generates code by traversing a syntax tree. It is still reasonable to call the Unicon translator a preprocessor, but it has many of the traits of a compiler.

### 27.1 Overview

The Unicon translator lives in `uni/unicon/`. In addition to many Unicon source files, it uses the external tools `iyacc` and `merr` to generate its parser and syntax error message tables, which depend on files `unigram.y` and `meta.err`, respectively. Unicon is written in Unicon, posing a bootstrapping problem. When building from sources, some of the `.icn` files can be translated by `icont` (the Icon translator, a C program). Those files that require Unicon itself in order to compile are included in precompiled object format (in `.u` files) in order to solve the bootstrapping problem.

### 27.2 Lexical Analysis

Unicon's lexical analyzer is adapted from a hand-written lex-compatible scanner written by Bob Alexander and used in the Jcon Java-based implementation of Icon. Some of its design is borrowed from the original Icon lexical analyzer (which is handwritten C code). It would be interesting to replace Unicon's lexical analyzer with a machine generated lexical analyzer to reduce the amount of compiler source code to maintain. The lexical analyzer consists of a function `yylex()` located in `unicon/uni/unicon/unilex.icn`, about 500 lines of code.

### 27.2.1 Lex-compatible API

The global declarations that exist in order to provide a Lex-compatible API include:

```
$include "ytab_h.icn"           # yacc's token categories
global yytext                   # lexeme
global yyin                     # source file we are reading
global yytoken                  # token (a record)
global yylineno, yycolno, yyfilename # source location
```

### 27.2.2 Character Categories

The lexical analyzer uses several csets for different character categories beyond the built-in ones:

```
global O, D, L, H, R, FS, IS, W, idchars
```

```
procedure init_csets()
  O := '01234567'
  D := &digits
  L := &letters ++ ' _ '
  H := &digits ++ 'abcdefABCDEF'
  R := &digits ++ &letters
  FS := 'fFIL'
  IS := 'uUIL'
  W := 't\w'
  idchars := L ++ D
end
```

### 27.2.3 The Token Type

The record type storing each token's information just bundles together the syntactic category (an integer), lexeme (a string), and location at which the token occurred. This is pretty minimalist.

```
record token(tok, s, line, column, filename)
```

### 27.2.4 Error Handling and Debugging

Several remaining global variables are mainly used for error handling, and for debugging the lexical analyzer itself.

### 27.2.5 Reserved Words

Global `reswords()` creates and becomes a table holding the Unicon reserved words. For each word, a pair of integers [tokenflags, category] is kept. The tokenflags indicate whether the token allows semi-colon insertion if a newline immediately precedes it (Beginner) or comes after it (Ender); see section 26.2.7 below. Language design note: tables in this language need a literal format.

```

procedure reswords()
static t
initial {
    t := table([Beginner+Ender, IDENT])

    t["abstract"] := [0, ABSTRACT]
    t["break"] := [Beginner+Ender, BREAK]
    t["by"] := [0, BY]
    ...
    t["to"] := [0, TO]
    t["until"] := [Beginner, UNTIL]
    t["while"] := [Beginner, WHILE]
}
return t
end

```

### 27.2.6 Big-inhale Input

A function, `yylex_reinit()` is called the first time `yylex()` is called, along with each time the compiler moves to process a new file named on the command line. Along with initializing the public API variables, this function reads in the entire file, in a single global string variable, cleverly named `buffer`. This allows extremely fast subsequent processing, which does no file I/O for each token, while avoiding complex buffering sometimes done to reduce file I/O costs in compilers.

This “big-inhale” model did not work well on the 128K PDP-11 UNIX computers Icon’s C implementation were developed on, but works well in this century. At present, the code assumes Unicon source files are less than a megabyte – a lazy programmer’s error. Although Unicon programs are much shorter than C programs, an upper limit of 1MB is bound to be reached someday.

```

procedure yylex_reinit()
    yytext := ""
    yylineno := 0
    yycolno := 1
    lastchar := ""

```

```

if type(yyin) == "file" then
    buffer := reads(yyin, 1000000)
else
    buffer := yyin
tokflags := 0
end

```

### 27.2.7 Semicolon Insertion

Icon and Unicon insert semicolons for the programmer automatically. This is an easy lexical analyzer trick. The lexical analyzer requires one token of lookahead. Between each two tokens, it asks: was there a newline? If yes, was the token before the newline one that could conceivably be the end of an expression, and was the token at the start of the new line one that could conceivably start a new expression? If it would be legal to do so, it saves the new token and returns a semicolon instead.

This little procedure is entirely hidden from the regular lexical analyzer code by writing that regular code in a helper function `yylex2()`, and writing the semicolon insertion logic in a `yylex()` function that calls `yylex2()` when it needs a new token.

Initialization for the `yylex()` function shows the static variables used to implement the one token of lookahead. If the global variable `buffer` doesn't hold a string anymore, `/buffer` will succeed and it must be that we are at end-of-file and should return 0.

```

procedure yylex()
static saved_tok, saved_yytext
local rv, ender
initial {
    if /buffer then
        yylex_reinit()
    }
    if /buffer then {
        if \debuglex then
            write("yylex() : 0")
        return 0
    }
}

```

If a semicolon was inserted the last time `yylex()` was called, the `saved_tok` will be the first token of the next line; it should be returned.

```

if \saved_tok then {
    rv := saved_tok
    saved_tok := &null
    yytext := saved_yytext
    yylval := yytoken := token(rv, yytext, yylineno, yycolno, yyfilename)
    if \debuglex then
        write("yylex() : ", tokenstr(rv), "\t", image(yytext))
    return rv
}

```

Otherwise, we should obtain the next token by calling `yylex2()`. We have to check for end of file, remember if the last token could end an expression, call `yylex2()`, and update buffer to be the smaller string remaining after the token.

```

ender := iand(tokflags, Ender)
tokflags := 0
if *buffer=0 then {
    buffer := &null
    if \debuglex then
        write("yylex() : EOFX")
    return EOFX
}
buffer ? {
    if rv := yylex2() then {
        buffer := tab(0)
    }
    else {
        buffer := &null
        yytext := ""
        if \debuglex then
            write("yylex() : EOFX")
        return EOFX
    }
}

```

After fetching a new token, we have to decide whether to insert a semicolon or not. This is based on global variable `ender` (whether the previous token could end an expression) and global variable `tokflags` (which holds both whether the current token could begin an expression, and whether a newline occurred between the last token and the current token). `iand()` is a bitwise AND, equivalent to C language `&` operator, used to pick bits out of a set of boolean flags encoded as bits within an integer.

```

if ender~=0 & iand(tokflags, Beginner)~=0 & iand(tokflags, Newline)~=0 then {
    saved_tok := rv
    saved_yytext := yytext
    yytext := ";"
    rv := SEMICOL
}

```

Returning a token requires allocation of a token() record instance, which is stored in a global variable.

```

yyval := yytoken := token(rv, yytext, yylineno, yycolno, yyfilename)
if \debuglex then
    write("yylex() : ", tokenstr(rv), "\t", image(yytext))
return rv
end

```

### 27.2.8 The Real Lexical Analyzer Function, yylex2()

This function maintains a table of functions, calling a helper function depending on what the first character in the token is.

```

procedure yylex2()
static punc_table
initial {
    init_csets()
    reswords := reswords()
    punc_table := table(uni_error)
    punc_table[""] := do_literal
    punc_table["\"] := do_literal
    punc_table["!"] := do_bang
    punc_table["%"] := do_mod
    ...
    punc_table["$"] := do_dollar
    every punc_table[!&digits] := do_digits
    every punc_table["_" | !&letters] := do_letters
}

```

The main lexical analyzer code strips comments and whitespace, and calls the function table for the first non-whitespace character it finds. Note support for #line directives, and the use of string scanning.

```

yycolno += *yytext

repeat {
  if pos(0) then fail
  if
    = "#" then {
      if = "line " then {
        if yylineno := integer(tab(many(&digits))) then {
          = "\"
          yyfilename := tab(find("\"")|0)
        }
      }
      tab(find("\n") | 0)
    next
  }
  if = "\n" then {
    yylineno += 1
    yycolno := 1
    if tokflags < Newline then
      tokflags += Newline
    next
  }
  if tab(any(' ')) then { yycolno += 1; next }
  if tab(any("\v\l")) then { next }
  if tab(any("\t")) then {
    yycolno += 1
    while (yycolno-1) % 8 ~= 0 do yycolno += 1
  next
}

yytext := move(1)
return punc_table[yytext]()
}
end

```

The functions in the punctuation table select integer codes and match the rest of the lexeme. `do_comma()` illustrates an unambiguous token selection, while `do_plus()` illustrates a more common case where the "+" character could start any of 5 different tokens depending on the character(s) that follow it. Tokens starting with "letters" are looked up in a reserved words table, which tells whether they are special, or just a variable name.

```

procedure do_comma()
  return COMMA
end

procedure do_plus()
  if yytext ||:= ":" then {
    if yytext ||:= "=" then { return AUGPLUS }
    return PCOLON
  }
  if yytext ||:= "+" then {
    if yytext ||:= ":" then {return AUGUNION}
    return UNION
  }
  tokflags += Beginner
  return PLUS
end

procedure do_letters()
  yytext ||:= tab(many(idchars))
  x := reswords[yytext]
  tokflags += x[1]
  return x[2]
end

```

## 27.3 The Unicon Parser

Unicon's parser is written using a YACC grammar; a graduate student (Ray Pereda) modified Berkeley's public domain version of YACC (byacc) to generate Unicon code, following in the footsteps of someone who had earlier modified it to generate Java. The Unicon parser lives in `uni/unicon/unigram.y` in the source distribution (22kB, 700 lines, 119 terminals, 71 nonterminals). Unicon's YACC grammar was obtained by copying the Icon grammar, and adding Unicon syntax constructs. Prior to this time the object-oriented dialect of Icon was called Idol and really was a line-oriented preprocessor instead of a compiler.

The start symbol for the grammar is named `program`, and the semantic action code fragment for this nonterminal calls the rest of the compiler (semantic analysis and code generation) directly on the root of the syntax tree, rather than storing it in a global variable for the `main()` procedure to examine.

```

program : decls EOFX { Progend($1); } ;

```

Many context free grammar rules are recursive, with an empty production to terminate the recursion. The rule for declarations is typical:

```
decls : { $$ := EmptyNode }
      | decls decl {
          if yynerrs = 0 then iwrites(&errout, ".")
          $$ := node("decls", $1, $2)
        } ;
```

The "semantic action" (code fragment) for every production rule builds a syntax tree node and assigns it to \$\$ for the nonterminal left-hand side of the rule.

Another common grammar pattern is a production rule that has many different alternatives, such as the one for individual declarations:

```
decl : record
      | proc
      | global
      | link
      | package
      | import
      | invocable
      | cl
      ;
```

For such "unary" productions, child's syntax tree node suffices for the parent, no new tree node is needed.

Some nonterminals mostly correspond to a specific sequence of terminals, as is the case for package references:

```
packageref : IDENT COLONCOLON IDENT { $$ := node("packageref", $1,$2,$3) }
            | COLONCOLON IDENT { $$ := node("packageref", $1,$2) }
            ;
```

The lexical analyzer has already constructed a valid "leaf" for each terminal symbol, so if a production rule has only one terminal symbol in it, for a syntax tree we can simply use the leaf for that nonterminal (for a parse tree, we would need to allocate an extra unary internal node):

```
Inkfile : IDENT ;
         | STRINGLIT ;
```

The expressions (which comprise about half of the grammar) use a separate nonterminal for each level of precedence instead of YACC's declarations for handling precedence (%left, %right, etc). The Icon and Unicon grammars approach 20 levels of nonterminals. A typical rule looks like:

```
expr6 : expr7 ;
       | expr6 PLUS expr7 { $$ := node("Bplus", $1,$2,$3); } ;
       | expr6 DIFF expr7 { $$ := node("Bdiff", $1,$2,$3); } ;
       | expr6 UNION expr7 { $$ := node("Bunion", $1,$2,$3); } ;
```

```
| expr6 MINUS expr7 { $$ := node("Bminus", $1,$2,$3); } ;
```

The "B" stands for "binary", to distinguish these operators from their unary brethren. The 20 levels of nonterminals approach is inherited from Icon and probably makes the parser larger than it has to be, but taking these nonterminals out doesn't seem to help much.

### 27.3.1 Syntax Error Handling

Icon employed a relatively clever approach to doing syntax error messages with YACC — the parse state at the time of error is enough to do fairly good diagnoses. But, every time the grammar changed, the parse state numbers could change wildly. For Unicon I developed the Merr tool, which associates parse error example fragments with the corresponding diagnostic error message, and detects/infers the parse state for you, reducing the maintenance problem when changing the grammar. Merr also considers the current input token in deciding what error message to emit, making it fundamentally more precise than Icon's approach.

## 27.4 The Unicon Preprocessor

The Icon language originally did not include any preprocessor, but eventually, a simple one was introduced, with ability to include headers, define symbolic constants (macros without parameters), and handle conditional compilation (ifdef). The preprocessor implementation in Unicon was written by Bob Alexander, and came to Unicon by way of Jcon, an Icon-to-JVM translator. This preprocessor is written in a single 600+ line file, uni/unicon/preproce.icn.

The external public interface of the preprocessor is line-oriented, consisting of a generator `preproc(filename, predefinedsyms)` which suspends each line of the output, one after another. Its invocation from the `main()` procedure looks like:

```
yyin := ""
every yyin ||:= preprocessor(fName, uni_predefs) do
  yyin ||:= "\n"
```

Since the preprocessor outputs line-by-line, there is a mismatch between it and the lexical analyzer's big-inhale model. The preprocessor could be modified to fit better with the lexical analyzer or vice versa.

The preprocessor function takes the filename to read from, along with a table of predefined symbols which allows the preprocessor to respond to lines like

```
$ifdef _SQL
```

based on what libraries are available and how Unicon was built on a given platform.

The `preprocessor()` function itself starts each call off with initializations:

```
static nonpunctuation
initial {
```

```

    nonpunctuation := ≤&letters ++ &digits ++ ' \t\f\r'
}

```

```

preproc_new(fname,predefined_syms)

```

The initialization code opens `fname`, creates empty stacks to keep track of nested `$ifdef`'s and `$include`'s, initializes counters to 0 and so forth.

The preprocessor is line-oriented. For each line, it looks for a preprocessor directive, and if it does not find one, it just scans for symbols to replace and returns the line. The main loop looks like

```

while line := preproc_read() do line ? {
    preproc_space()    # eat whitespace
    if ("#" & match("line")) | ("$" & any(nonpunctuation)) then {
        suspend preproc_scan_directive()
    }
    else {
        &pos := 1
        suspend preproc_scan_text()
    }
}

```

The procedures `preproc_scan_directive()` and `preproc_scan_text()` work on special and ordinary lines, respectively. The line is not a parameter because it is held in the current string scanning environment. The `preproc_scan_directive()` starts by discarding whitespace and identifying the first word on the line (which must be a valid preprocessor directive). A case expression handles the various directives (`define`, `undef`, `ifdef`, etc.). Defined symbols are stored in a table. `$ifdef` and `$ifndef` are handled using a global variable `preproc_if_state` to track the boolean conditions. A count of `$ifdef`'s is maintained, in order to handle matching `endif`'s.

Include files are handled using a stack, but an additional set of filenames is kept to prevent infinite recursion when files include each other. When a new include directive is encountered it is checked against the `preproc_include_set` and if OK, it is opened. The including file (and its associated name, line, etc) are pushed onto a list named `preproc_file_stack`. It is possible to run out of open files under this model, although this is not easy under modern operating systems.

Include files are searched on an include file path, consisting of a list of directories given on an optional environment variable (`LPTH`) followed by a list of standard directories. The standard directories are expected to be found relative to the location of the virtual machine binaries.

The procedure `preproc_scan_text` has the relatively simple job of replacing any symbols by their definitions within an ordinary source line. Since macros do not have parameters, it is vastly simpler than in a C preprocessor. The main challenges are to avoid macro substitutions when a symbol is in a comment or within quotes (string or cset literals). An additional issue is to handle multiline string literals, which occur in Icon when a string literal is not closed on a line, and instead the line ends with an underscore indicating that it is continued on the next line. Skipping over quoted

text sounds simple, but is trickier than it looks. Escape characters mean you can't just look for the closing quote without considering what comes before it, and you can't just look at the preceding character since it might have been escaped, as in "\". The code looks similar to:

```
repeat {
  while tab(upto("'"'\')) do {
    case move(1) of {
      "\"": move(1)
      default: {
        break break
      }
    }
  }
  # ...
  if not match("_",-1) then
    break
  ⊂&subject := preproc_read() | fail
  # ...
}
```

The code in `preproc_read()` for reading a line does a regular Icon `read()`; end of file causes the preprocessor `file_stack` to be popped for the previous file's information. Performance has not been perceived as a significant problem, but it would be interesting to convert `preproc_read()` to use a big-inhale model to see if any statistical difference could be observed. When an include is encountered under a big-inhale, the saved state would contain the string of remaining file contents, instead of the open file value.

## 27.5 Semantic Analysis

The Unicon translator's semantic analysis is minimal, and revolves mainly around object-oriented features such as inheritance and package imports. Before we can look at those things, we need to look at the syntax tree structure.

In conventional YACC, a `%union` declaration is necessary to handle the varying types of objects on the value stack including the type used for syntax tree nodes, but `iyacc` has no need of this awkward mechanism: the value stack like all structure types can hold any type of value in each slot. Similarly, tree nodes can hold children of any type, potentially eliminating any awkwardness of mixing tokens and internal nodes. Of course, you do still have to check what kind of value you are working with.

### Parse Tree Nodes

uni/unicon/tree.icn contains procedures to handle the syntax tree node data type, including both the following declaration and the yyprint() traversal function we'll be discussing in today's lecture.

```
record treenode(label, children)
```

holds one node worth of information. For convenience, a procedure node(label, kids[]) takes an arbitrary number of parameters and constructs the list of children for you. Leaves have a null children field.

### "Code Generation" in the Unicon Translator

In a regular preprocessor, there is no code generation, there is a text-filter model in which the preprocessor writes out (modified) versions of the lines it reads in. In the Unicon translator, the code that is written out is produced by a traversal of the syntax tree. The same technique might be used by a "pretty printer". We will explore this aspect of the Unicon translator as the best available demonstration of working with Unicon syntax trees. Later on we will consider more "real" code generation in the virtual machine and the optimizing compiler.

Earlier we saw that the start symbol of the Unicon grammar had a semantic action that called a procedure Progend(). We will cover most of that procedure next week since it is all about object-orientation, but at the end Progend(), a call to yyprint() performs the tree traversal for code generation. A classic tree traversal pattern would look like:

```
procedure traverse(node)
  if node is an internal node {
    every child := ! node.children do traverse(child)
    generate code for this internal node (postfix)
  }
  else
    generate code for this leaf
end
```

The code generator traversal yyprint() is a lot more complicated than that, but fits the general pattern. The main work done at various nodes is to write some text to the output file, yyout. Most ordinary internal nodes are of type treenode as described above. But because there are several kinds of internal nodes and several kinds of leaves, the "if node is an internal node" is implemented as a case expression. Besides a regular treenode, the other kinds of internal nodes are objects of type declaration, class, and argument list. For regular treenodes, another case expression on the node's label field is used to determine what kind of code to generate, if any, besides visiting children and generating their code.

The default behavior for an internal node is to just visit the children, generating their code. For ordinary syntax constructs (if, while, etc.) this works great and a copy of the code is written out, token by token. But several exceptions occur, mainly for the pieces of Unicon syntax that extend Icon's repertoire. For example, packages and imports are not in Icon and require special treatment.

```
procedure yyprint(node)
  static lasttok
```

```

case type(node) of {
  "treenode" : {
    case node.label of {
      "package": { } # handled by semantic analysis
      "import": { print_imports(node.children[2]) }
      # implement packages via name mangling
      "packageref": {
        if *node.children = 2 then
          yyprint(node.children[2]) # ::ident
        else { # ident :: ident
          yyprint(node.children[1])
          writes(yyout, "___")
          outcol += ((* writes(yyout, node.children[3].s)) + 2)
        }
      }
    }
  }
}

```

New syntax constructs such as procedure parameter defaults and type restrictions, and variable initializers, are other examples where the default traversal would output things illegal in Icon. They are implemented by skipping some of the children (assignment and value) in the regular pass, and adding extra code elsewhere, discussed below.

```

"varlist2"|"stalist2": { yyprint(node.children[1]) }
"varlist4"|"stalist4": {
  yyprint(node.children[1])
  yyprint(node.children[2])
  yyprint(node.children[3])
}

```

Much of this special logic is orchestrated by the code for traversing a procedure; it can visit its arguments and variable declarations and apply special rules to them.

```

"proc": {
  yyprint(node.children[1])
  every yyprint(node.children[2 to 3])
  if exists_statlists(node.children[3]) then {
    ini := node.children[4]
    yyprint("\ninitial {")
    if ini ~=== EmptyNode then { # append into existing initial
      yyprint(ini.children[2])
      yyprint(";\n")
    }
    yyprint("\n}")
  }
  yyprint("\n}")
}

```

```

    }
  else
    every yyprint(node.children[4])
    (node.children[1].fields).coercions()
    yyvarlists(node.children[3])
    yyprint(node.children[5])
    yyprint(node.children[6])
  }

```

The default behavior of visiting one's children is very simple, as is the handling of other kinds of internal nodes, which are objects. For the objects, a method Write() is invoked.

```

"error": fail
default:
  every yyprint(lnode.children)
}
"declaration__state" | "Class__state" | "argList__state":
  node.Write(yyout)

```

The outer case expression of yyprint() continues with various kinds of leaf (token) nodes. These mainly know how to write their lexemes out. But, a lot of effort is made to try to keep line and column number information consistent. Variables outline and outcol are maintained as each token is written out. Integers and string literals found in the syntax tree are written out as themselves. Since they have no attached lexical attributes, they are a bit suspect in terms of maintaining debugging consistency. It turns out the reason they occur at all, and the reason they have no source lexical attributes, is that artificial syntax subtrees are generated to handle certain object-oriented constructs, and within those subtrees strings and integers may be placed, which do not correspond to anywhere in the source code.

```

"integer": {
  writes(yyout, node); outcol += *string(node)
}
"string": {
  node ? {
    while writes(yyout, tab(find("\n")+1)) do {
      outline+=1; outcol:=1;
    }
    node := tab(0)
  }
  writes(yyout, node); outcol += *node
}

```

"Normally", tokens are written out at exactly the line and column they appear at in the source code. But a myriad of constructs may bump them around. If the output falls behind (in lines,

or columns) extra whitespace can be inserted to stay in sync. If output gets ahead by lines, a `#line` directive can back it up, but if output gets ahead by columns, there is nothing much one can do, except make sure subsequent tokens don't accidentally get attached/concatenated onto earlier tokens. This occurs, for example, when the output code for an object-oriented construct in an expression is longer than the source expression, perhaps due to name mangling. Specific token combinations are checked, but the list here may be incomplete (possible BUG!). For source tokens, not only might the line and column change, the filename could be different as well.

```
"token": {
  if outfilename ~= node.filename | outline > node.line then {
    write(yyout, "\n#line ", node.line-1, " \'", node.filename, "\'")
    outline := node.line
    outcol := 1
    outfilename := node.filename
  }
  while outline < node.line do {
    write(yyout); outline += 1; outcol := 1
  }
  if outcol >= node.column then {
    # force space between idents and reserved words, and other
    # deadly combinations (need to add some more)
    if ((\lasttok).tok = (IDENT|INTLIT|REALLIT) & reswords[node.s][2]~=IDENT)|
      ((\lasttok).tok = NMLT) & (node.tok = MINUS)) |
      ((\lasttok).tok = node.tok = PLUS) |
      ((\lasttok).tok = node.tok = MINUS) |
      ((reswords[(\lasttok).s][2]~=IDENT) & (node.tok=(IDENT|INTLIT|REALLIT)))|
      ((reswords[(\lasttok).s][2]~=IDENT) & (reswords[node.s][2]~=IDENT))
    then
      writes(yyout, " ")
  }
  else
    while outcol < node.column do { writes(yyout, " "); outcol += 1 }
  Most tokens' lexemes are finally written out by writing node.s:
  writes(yyout, node.s)
  outcol += *node.s
  lasttok := node
}
"null": { }
default: write("its a ", type(node))
}
```

```
end
Keywords
```

Besides the large set of interesting reserved words, Icon and Unicon have another set of pre-defined special words called *keywords*. These words are prefixed by an ampersand, for example, &subject holds the current "subject" string being examined by string scanning. A procedure Keyword(x1,x2) semantically checks that an identifier following a unary ampersand is one of the valid keyword names. The valid names are kept in a set data structure.

## 27.6 Object Oriented Facilities

Unicon features classes, packages, and a novel multiple inheritance mechanism. These items are implemented entirely within the Unicon translator. The Icon virtual machine thusfar has only the slightest of extensions for object-orientation, specifically, the dot operator has been extended to handle objects and method invocation.

The Unicon OOP facilities were originally prototyped as a semester class project in a "special topics" graduate course. Writing the prototype in a very high-level language like Icon, and developing it as a preprocessor with name mangling, allowed the initial class mechanism to be developed in a single evening, and a fairly full, usable system with working inheritance to be developed in the first weekend. By the end of the semester, the system was robust enough to write it in itself, and it was released to the public shortly afterwards as a package for Icon called "Idol". Many many improvements were made after this point, often at the suggestion of users.

An initial design goal was to make the absolute smallest additions to the language that were necessary to support object-orientation. Classes were viewed as a version of Icon's record data type, retaining its syntax for fields (member variables), but appending a set of associated procedures. Because records have no concept of public and private, neither did classes. Another graduate student criticized this lack of privacy, and for several versions, everything was made private unless an explicit public keyword was used. But eventually support for privacy was dropped on the grounds that it added no positive capabilities and was un-Iconish. The existence of classes with hundreds of "getter" and "setter" methods was considered a direct proof that "private" was idiotic in a rapid prototyping language.

### The Code Generation Model for Classes

"unicon -E foo" will show you what code is generated for Unicon file foo.icn. If foo.icn contains classes, you can enjoy the code generation model and experiment to see what it does under various circumstances. As a first example, consider

```
class A(x,y)
  method m()
    write("hello")
end
```

end

These five lines generate 25 lines for Icon to translate into virtual machine code. The first two lines are line directives showing from whence this source code originated:

```
#line 0 "/tmp/uni13804206"
```

```
#line 0 "a.icn"
```

Global declarations (including procedures) would be passed through the preprocessor pretty nearly intact, but for the class, we get a bunch of very different code. Methods are written out, with names mangled to a classname\_methodname format.

```
procedure A_m(self)
```

```
#line 2 "a.icn"
```

```
  write("hello");
```

```
end
```

Two record types are defined, one for the class instances and one for the "methods vector", or "operation record". The methods vector is instantiated exactly once in a global variable in classname\_\_oprec format.

```
record A__state(__s,__m,x,y)
```

```
record A__methods(m)
```

```
global A__oprec
```

The default constructor for a class takes fields as parameters and uses them directly for initialization purposes. The first time it is called, a methods vector is created. Instances are given a pointer to themselves in an \_\_s field (mainly for historical reasons) and to the methods vector in an \_\_m field. Current NMSU grad student Sumant Tambe did an independent study project to get rid of \_\_s and \_\_m with partial success, but his work is not finished or robust enough to be enabled by default.

```
procedure A(x,y)
```

```
local self,clone
```

```
initial {
```

```
  if /A__oprec then Ainitialize()
```

```
}
```

```
self := A__state(νll,A__oprec,x,y)
```

```
self.__s := self
```

```
return self
```

```
end
```

```
procedure Ainitialize()
```

```
  initial A__oprec := A__methods(A_m)
```

```
end
```

Symbols and Scope Resolution

One of the basic aspects of semantic analysis is: for each variable, where was it declared, so we can identify its address, etc. Unicon inherits from Icon the curious convenience that variables do not have to be declared: they are local by default. This feature is implemented by deferring the local vs. global decision until link time, so the Unicon translator has no local vs. global issues. Class variables, however, have to be identified, and looked up relative to the implicit "self" variable. A family of procedures in uni/unicon/tree.icn with names starting "scopecheck" go through the syntax tree looking for such class variables. Like most tree traversals, this is a recursive process, and since local and parameter declarations override class variables, there are helper functions to walk through subtrees building mini-symbol tables such as `local_vars` in `scopecheck_proc(node)`:

```
# Build local_vars from the params and local var expressions.
```

```
local_vars := set()
```

```
extract_identifiers(node.children[1].fields, local_vars)
```

```
extract_identifiers(node.children[3], local_vars)
```

Eventually, every identifier in every expression is checked against `local_vars`, and if not found there, against the class variables stored in a variable `self_vars`:

```
self_vars := set()
```

```
every insert(self_vars, c.foreachmethod().name)
```

```
every insert(self_vars, c.foreachfield())
```

```
every insert(self_vars, (!c.ifields).ident)
```

```
every insert(self_vars, (!c.imethods).ident)
```

For an IDENT node, the tests boil down to:

```
if node.tok = IDENT then {
  if not member(\local_vars, node.s) then {
    if member(\self_vars, node.s) then
      node.s := "self." || node.s
    else
      node.s := mangle_sym(node.s)
  }
}
```

Undeclared locals and globals are mangled to include the current package name if there is one.

## Inheritance

Inheritance means: creating a class that is similar to an existing class. In object-oriented literature there is "abstract inheritance" in which a class supports all the same operations with the same signatures, and there is concrete inheritance in which actual code is shared. Early object-oriented languages supported only concrete inheritance, while more recent languages tend to discourage it. Unicon is not typed at compile time, so abstract inheritance is not a big deal. There are abstract methods, and classes whose every method is abstract, but the use of abstract is mainly for documentation: subclass authors must provide certain methods. Anyhow, the syntax of inheritance in Unicon is

```
class subclass : super1 : super2 : ... ( ...fields... )
```

The semantics of inheritance, and particularly of multiple inheritance, are interesting in Unicon; the implementation is relatively simple. An example of inheritance is given by class `Class`, from `uni/unicon/idol.icn`

```
class declaration(name,fields,tag,lptoken,rptoken)
...
end
...
class Class : declaration (supers,
    methods,
    text,
    imethods,
    ifields,
    glob,
    linkfile,
    dir,
    unmangled_name,
    supers_node)
```

Unique perspective on inheritance in Unicon comes from the actual acquisition of inherited data fields and methods by the subclass. Some object-oriented languages do this inheritance "by aggregation", creating a copy of the superclass in the subclass. This is fine, but it makes "overriding" an anomaly, when overriding the parent with new/different behavior is entirely routine. Unicon instead inherits by the child looking for things in the parent (and the parent's parent, etc.) that they don't already have. In the above example, class `declaration` effectively appends 5 fields from class `declaration` onto the end of its field list. The generated code for instances looks like

```
record Class__state(__s,__m,
    supers,methods,text,imethods,ifields,
    glob,linkfile,dir,unmangled_name,supers_node,
    name,fields,tag,lptoken,rptoken)
```

The inheritance semantics is called "closure based" because the process of looking for things to add from parent superclasses iterates until no new information can be added, after which the subclass is said to be closed on its parents. Other forms of closure appear frequently in CS.

### 27.6.1 Implementing Multiple Inheritance in Unicon

The actual code in the Unicon translator is, by analogy to transitive closure, looking for things to inherit via a depthfirst traversal of the inheritance graph. Multiple inheritance can be separated out into two portions:

1. a method `transitive_closure()` that finds all superclasses and provides a linearization of them, flattening the graph into a single ordered list of all superclasses
2. a method `resolve()` that walks the list and looks for classes and fields to add.

Method `transitive_closure()` is one of the cleaner demonstrations of why Unicon is a fun language in which to write complex algorithms. It is walking through a class graph, but by the way it is not recursive.

```
method transitive_closure()
  count := supers.size()
  while count > 0 do {
    added := taque()
    every sc := supers.foreach() do {
      if /(super := classes.lookup(sc)) then
        halt("class/transitive_closure: _
              couldn't find superclass ",sc)
      every supersuper := super.foreachsuper() do {
        if / self.supers.lookup(supersuper) &
            /added.lookup(supersuper) then {
          added.insert(supersuper)
        }
      }
    }
    count := added.size()
    every self.supers.insert(added.foreach())
  }
end
```

Now, given that Unicon provides a depthfirst inheritance hierarchy semantics, what is wrong with this picture? The code is stable and hasn't needed changes in several years, so this question is not fishing for syntax bugs, or claiming that there is a bug. But there is something odd.

The method `resolve()` within class `Class` finds the inherited fields and methods from the linearized list of superclasses.

```
#
# resolve -- primary inheritance resolution utility
#
method resolve()
  #
  # these are lists of [class , ident] records
  #
```

```

self.imethods := []
self.ifields := []
ipublics := []
addedfields := table()
addedmethods := table()
every sc := supers.foreach() do {
  if /(superclass := classes.lookup(sc)) then
    halt("class/resolve: couldn't find superclass ",sc)
  every superclassfield := superclass.foreachfield() do {
    if /self.fields.lookup(superclassfield) &
      /addedfields[superclassfield] then {
      addedfields[superclassfield] := superclassfield
      put ( self.ifields , classident(sc,superclassfield) )
      if superclass.ispublic(superclassfield) then
        put( ipublics, classident(sc,superclassfield) )
    } else if \strict then {
      warn("class/resolve: ",sc," field ",superclassfield,
        "" is redeclared in subclass ",self.name)
    }
  }
}
every superclassmethod := (superclass.foreachmethod()).name() do {
  if /self.methods.lookup(superclassmethod) &
    /addedmethods[superclassmethod] then {
    addedmethods[superclassmethod] := superclassmethod
    put ( self.imethods, classident(sc,superclassmethod) )
  }
}
every public := (!ipublics) do {
  if public.Class == sc then
    put (self.imethods, classident(sc,public.ident))
}
}
end

```

### Class and Package Specifications

In the "old days" of Unicon's ancestor Idol, you could only inherit from a class that appeared in the same source file. Anything else poses a librarian's problem of identifying from what file to inherit. Java, for instances, takes a brute-force approach of one class per file.

Unicon generates in each source directory an NDBM database (named `uniclass.dir` and `uniclass.pag`) that includes a mapping from class name to: what file the class lives in, plus, what superclasses, fields, and methods appear in that class. From these specifications, "link" declarations are generated for superclasses within subclass modules, plus the subclass can perform inheritance resolution. The code to find a class specification is given in `idol.icn`'s `fetchspec()`. A key fragment looks like

```

    if f := open(dir || "/" || env, "dr") then {
        if s := fetch(f, name) then {
            close(f)
            return db_entry(dir, s)
        }
        close(f)
    }

```

Unicon searches for "link" declarations in a particular order, given by the current directory followed by directories in an `IPATH` (Icode path, or perhaps Icon path) environment variable, followed by system library directories such as `ipl/lib` and `uni/lib`. This same list of directories is searched for inherited classes.

The string stored in `uniclass.dir` and returned from `fetch()` for class `Class` is:

```

idol.icn
class Class : declaration(supers,methods,text,imethods,ifields,glob,linkfile,dir,unmangled_name,s
ismethod
isfield
Read
ReadBody
has_initially
ispublic
foreachmethod
foreachsuper
foreachfield
isvarg
transitive_closure
writedecl
WriteSpec
writemethods
Write
resolve
end

```

## 27.6.2 Unicon's Progend() revisited

Having presented scope resolution, inheritance, and importing packages and inheriting classes from other files via the uniclass.dir NDBM files, we can finally show the complete semantic analysis in the Unicon compiler, prior to writing out the syntax tree as Icon code:

```

procedure Progend(x1)

    package_level_syms := set()
    package_level_class_syms := set()
    set_package_level_syms(x1)
    scopecheck_superclass_decs(x1)

    outline := 1
    outcol := 1
    #
    # export specifications for each class
    #
    native := set()
    every cl := classes.foreach_t() do {
        cl.WriteSpec()
        insert(native, cl)
    }
    #
    # import class specifications, transitively
    #
    repeat {
        added := 0
        every super := ((classes.foreach_t()).foreachsuper() | !imports) do {
            if /classes.lookup(super) then {
                added := 1
                readspecc(super)
                cl := classes.lookup(super)
                if /cl then halt("can't inherit class '",super,"'")
                iwrite(" inherits ", super, " from ", cl.linkfile)
                writelink(cl.dir, cl.linkfile)
                outline += 1
            }
        }
    }
    if added = 0 then break
}

```

```

#
# Compute the transitive closure of the superclass graph. Then
# resolve inheritance for each class, and use it to apply scoping rules.
#
every (classes.foreach_t()).transitive_closure()
every (classes.foreach_t()).resolve()

scopecheck_bodies(x1)

if \thePackage then {
  every thePackage.insertsym(!package_level_syms)
}

#
# generate output
#
yyprint(x1)
write(yyout)

```

### 27.6.3 Other OOP Issues

The primary mechanisms for object-oriented programming that we have discussed so far include: classes, method invocation, inheritance. There were certainly a few parts we glossed over (like how `a$super.m()` is implemented.) The main way to look for additional issues we skipped is to read `uni/unicon/idol.icn`, which handles all the object-oriented features and comes from the original Idol preprocessor. Here are some thoughts from a scan of `idol.icn`:

- the preprocessor semi-parsed class and method headers in order to do inheritance. After the real (YACC-based) parser was added, I hoped to remove the parsing code, but it is retained in order to handle class specifications in the `uniclass.dir` NDBM files
- The classes in `idol.icn` correspond fairly directly to major syntax constructs; the compiler itself is object-oriented.
- Packages are a "virtual syntax construct": no explicit representation in the source, but stored in the `uniclass.dir` database
- There is a curious data structure, a tabular queue, or *taque*, that combines (hash) table lookup and preserves (lexical) ordering.
- Aggregation and delegation patterns are used a lot. A class is an aggregate of methods, fields, etc. and delegates a lot of its work to objects created for subparts of its overall syntax.

### **27.6.4 On Public Interfaces and Runtime Type Checking**

Object-oriented facilities are usually discussed in the context of large complex applications where software engineering is an issue. We don't usually need OOP for 100 line programs, but for 10,000+ line programs it is often a big help.

Besides classes and packages, Unicon adds to Icon one additional syntax construct in support of this kind of program: type checking and coercion of parameters. Parameters and return values are the points at which type errors usually occur, during an integration phase in a large project where one person's code calls another. The type checking and coercion syntax was inspired by the type checks done by the Icon runtime system at the boundary where Icon program code calls the C code for a given function or operator.

One additional comment about types is that the lack of types in declarations for ordinary variables such as "local x" does not prevent the Icon compiler `iconc` from determining the exact types of well over 90% of uses at compile time using type inference. Type checking can generally be done at compile time even if variable declarations do not refer to types... as long as the type information is available across file and module boundaries.

# Chapter 28

## Networking, Messaging and the POSIX Interface

Unicon's system interface is greatly enriched compared with Icon, primarily in that it treats Internet connections and Internet-based applications as ubiquitous, and extends the file type with appropriately high-level capabilities. Fundamental TCP and UDP connections are a breeze using the networking facilities, and common application-level protocols are supported via the messaging facilities (see also the X11 graphics facilities and the SQL/ODBC database facilities for examples where application-level networking is provided in Unicon). Portions of this chapter related to the messaging facilities were contributed by their author, Steve Lumos.

### 28.1 Networking Facilities

#### 28.1.1 Sockets in the Unicon File Functions

UNIX file abstractions allow certain low-level file I/O operations to be performed across either files or network sockets. Unicon's treatment of network connections as a special type of file uses the same abstraction, but Icon's existing file operations are written in terms of the higher-level buffered file I/O in ANSI C.

In general, the file operations have to call different underlying C calls depending on what kind of file is being used. File values in Unicon have a status word, and that word has various bits to indicate whether the file is really a network connection, graphics window, database, etc.

#### 28.1.2 Simultaneous Input from Different File Types

Modern applications may need to allow asynchronous input from all types of files. Unicon's `select()` originally used UNIX C's `select()` function as-is to handle input from various network connections,

including X Windows GUI input. MS Windows required an elaborate alternative to be developed, since window input events do not arrive on file descriptors. Eventually, the UNIX implementation was also migrated off the straight C `select()`, for greater flexibility in handling other file types. The general approach is to break the input list of input file handles out into sublists of each type, and handle them with separate calls, which must be repeated until some input is found. This polling approach can waste CPU. A small delay is included in the loop to prevent the CPU burning.

## 28.2 Messaging Facilities

### 28.2.1 The Transfer Protocol Library

All of the message facilities are handled by the transfer protocol library (libtp). This library provides an abstraction of the many different protocols (HTTP, SMTP, etc) into a clear and consistent API. Ease of adding support for new protocols and porting the entire library to new operating system interfaces were primary design goals. These goals are both accomplished by using the AT&T Labs discipline and method (DM) architecture described below.

### 28.2.2 Libtp Architecture

The key feature of the DM architecture is that it makes explicit two interfaces in the library: *disciplines* which hold system resources and define routines to acquire and manipulate them, and *methods* which define the higher-level algorithms used to access these resources. This model fits the problem of Internet transfer protocols nicely; the discipline abstracts the operating system interface to the network, and there is a method for each protocol that defines communication with a server only in terms of the discipline.

This architecture makes porting easy because you need only create a discipline for the new system, which means writing 9 functions. The only currently-existing discipline handling both the Berkeley Socket and WINSOCK APIs is only 400 lines long. Once a discipline exists, the new system immediately gains all of the supported protocols.

### 28.2.3 The Discipline

The discipline is a C structure whose members are pointers to functions:

```
typedef struct _tp_disc_s Tpdisc_t; /* discipline */

typedef int    (*Tpconnect_f)(char* host, u_short port, Tpdisc_t* disc);
typedef int    (*Tpclose_f)(Tpdisc_t* disc);
typedef ssize_t (*Tpread_f)(void* buf, size_t n, Tpdisc_t* disc);
```

```

typedef ssize_t (*Tpreadln_f)(void* buf, size_t n, Tpdisc_t* disc);
typedef ssize_t (*Tpwrite_f)(void* buf, size_t n, Tpdisc_t* disc);
typedef void*   (*Tpmem_f)(size_t n, Tpdisc_t* disc);
typedef int     (*Tpfree_f)(void* obj, Tpdisc_t* disc);
typedef int     (*Tpexcept_f)(int type, void* obj, Tpdisc_t* disc);
typedef Tpdisc_t* (*Tpnewdisc_f)(Tpdisc_t* disc);

struct _tpdisc_s
{
    Tpreadln_f readln; /* establish a connection */
    Tpclose_f  closef; /* close the connection */
    Tpread_f   readf;  /* read from the connection */
    Tpreadln_f readlnf; /* read a line from the connection */
    Tpwrite_f  writef; /* write to the connection */
    Tpmem_f    memf;   /* allocate some memory */
    Tpfree_f   freef;  /* free memory */
    Tpexcept_f exceptf; /* handle exception */
    Tpnewdisc_f newdiscf; /* deep copy a discipline */
    int        type; /* (not used currently) */
};

```

These functions define a complete API for acquiring and manipulating all of the system resources needed by all of the methods and (it is hoped) any conceivable method. By convention, every discipline function takes a pointer to the current discipline as its last argument. (Every method function takes a library handle which contains a pointer to the current discipline, so the discipline functions are always available when needed.) The `Tpdisc_t` is an abstract discipline. In practice, a new discipline will extend `Tpdisc_t` by at minimum adding some system dependent data such as a Unix file descriptor or Windows SOCKET\*. Here is the "Unix" discipline (it would be better called the socket discipline since it works for the Berkeley Socket API and WINSOCK on multiple systems):

```

struct _tpunixdisc_s
{
    Tpdisc_t tpdisc;
    int fd;
}

```

### 28.2.4 Exception Handling

The DM architecture defines a very useful convention for exception handling. Exceptions are passed as integers to the `exceptf` function along with some exception-specific data. The function can do

arbitrary processing and then return `{-1, 0, 1}`, which instructs the library to retry the operation (1), return an error to the caller (-1), or take some default action (0). Libtp uses constants `TP_TRYAGAIN`, `TP_RETURNERROR`, and `TP_DEFAULT`.

Although not as powerful as languages with true exceptions, the DM exception handling definitely serves to make the code more readable. In the Unix discipline, `exceptf` is used to aggregate all of the many, sometimes transient errors that can occur in network programming. For example, the Unix discipline's `readf` function is:

```
ssize_t unixread(void* buf, size_t n, Tpdisc_t* tpdisc)
{
    Tpunixdisc_t* disc = (Tpunixdisc_t*)tpdisc;

    size_t nleft;
    ssize_t nread;
    char* ptr = buf;

    nleft = n;
    while (nleft > 0) {
        if ((nread = read(disc->fd, ptr, nleft)) <= 0) {
            int action = tpdisc->exceptf(TP_EREAD, &nread, tpdisc);
            if (action > 0) {
                nread = 0;
                continue;
            }
            else if (action == 0) {
                break;
            }
            else {
                return (-1);
            }
        }

        nleft -= nread;
        ptr += nread;
    }
    return (n - nleft);
}
```

The Unix `read()` system call can return a positive number, indicating the number of bytes read, a negative number, indicated error, or zero, if end-of-file is reached (or a network connection is closed by the remote host). We consider the latter two cases exceptional, and ask `exceptf` what we

should do. An `exceptf` function is normally a large switch with one case for each exception. For `TP_EREAD`, it says:

```
case TP_EREAD:
    if (errno == EINTR) {
        return TP_TRYAGAIN;
    }
    else {
        ssize_t nread = (*(ssize_t*)obj);
        if (nread == 0) { /* EOF */
            return TP_DEFAULT;
        }
        else {
            return TP_RETURNERROR;
        }
    }
}
```

This may not seem very revolutionary, after all the code that calls `exceptf` and branches on its result is just as long as the exception handler itself. We aren't even gaining much code-reuse over the conventional method, which wraps system calls in another function with names like `Read()`. The real win here lies in the ability of the caller to replace or extend `exceptf` at runtime. You may have noticed that there is no code above to output an error message, `unixread()` simply returns -1 on errors. In fact, *the* standard and expected way to output errors is to override `exceptf`. The `wtrace` example shown [XXX: at the end somewhere?] uses the following:

```
Tpexcept_f tpexcept;
Tpdisc_t disc;

int exception(int e, void* obj, Tpdisc_t* disc)
{
    int rc = tpexcept(e, obj, disc);
    if (rc == TP_RETURNERROR) {
        if (errno != 0) {
            perror(url);
        }
    }
    else {
        switch (e) {
            case TP_HOST:
                fputs(url, stderr);
                fputs(": Unknown host\n", stderr);
                break;
            default:
```

```

        fputs(url, stderr);
        fputs(": Error connecting\n", stderr);
    }
}
exit(1);
}
else {
    return rc;
}
}

```

Then instead of the usual:

```
tp = tp_new(<uri>, <method>, TpdUnix);
```

wtrace copies TpdUnix, saves and replaces the default exception handler, and then uses the copied discipline:

```
disc = tp_newdisc(TpdUnix);
```

```
tpexcept = disc->exceptf;
```

```
disc->exceptf = exception;
```

```
tp = tp_new(<uri>, <method>, disc);
```

In the same way, wtrace also overrides all of the read and write functions to provide a trace log of HTTP communications.

# Chapter 29

## ODBC Database Facilities

Unicon's ODBC facilities were initially implemented by Federico Balbi for Microsoft Windows platforms. Happily, ODBC has been widely ported and is one of Microsoft's more open and successful technical contributions.

### 29.1 Organization

The seven functions introduced for the ODBC interface are located in `fdb.r`. Over time it was discovered that the only function that matters very much is `sql()`, and the others are somewhat vestigial.

The underlying runtime system support functionality is in `rdb.r`. Initially, the runtime system support consisted primarily of an ODBC-specific error message function, `odbcerror()`, along with functions for opening and closing database connections. Early uses of the facilities led to the revelation that the vast majority of the interface consists of type conversion and packaging of the results of SQL queries in Unicon format, as records to be produced by calls to `fetch()`. Consequently, the longest and most interesting function in `rdb.r` turns out to be the function `dbfetch()` that helps the Unicon function `fetch()` to do its job.

In addition to the new files `fdb.r` and `rdb.r`, which together come to around 1000 lines of RTL code, the database facilities introduced changes to several existing source files, under `#ifdef ISQL` directives.

- `fdefs.h`: ODBC function definitions.
- `grttin.h`: fake type definitions for ODBC data types.
- `rextens.h`: `ISQLEnv` extern definition.
- `rmacros.h`: `Fs_ODBC` file status flag and ODBC error codes.

- `rproto.h`: contains `odbcerror` function definition.
- `rstructs.h`: `ISQLFile` definition (ODBC connection type).
- `sys.h`: ODBC header files inclusion (`windows.h` and `sqltext.h`).
- `fxposix.ri`: contains `fetch()`, defined also under `Dbm`
- `init.r`: ODBC Environment structure release.
- `omisc.r`: size operator (unary `*`) for ODBC file type.
- `data.r`: `runerr` error code for ODBC file mismatch.

## 29.2 ISQLFile type

In Unicon an ODBC connection to a database is treated as though similar to an open file. This tired metaphor, borrowed from UNIX and Plan 9 for all forms of I/O, is fundamentally flawed, since ODBC connections are not byte streams, nor are they text- or line-oriented. However, to the extent that the “file” abstraction is really a generic reference to all types of operating system data sources and sinks that must be opened and interacted with via read and write operations, the metaphor is apt.

Internally an ODBC connection is represented by the following C structure:

```
#ifdef ISQL                                /* ODBC support */
    struct ISQLFile {                      /* SQL file */
        SQLHDBC hdbc;                     /* connection handle */
        SQLHSTMT hstmt;                   /* statement handle */
        char *query;                       /* SQL query buffer */
        long qsize;                       /* SQL query buffer size */
        char *tablename;
        struct b_proc *proc;               /* record constructor for current query */
        int refcount;
        struct ISQLFile *previous, *next;
    };
#endif
```

The field `hdbc` is used to keep the connection information associated to a particular `ISQLFile` file. `hstmt` is the statement structure that saves the results or dataset returned by an ODBC operation. The design of the interface is table oriented, which means that for each table we open a new connection.

In the future we will consider the possibility to associate a file to a database. This would let us open a connection for each database and share the same connection for each table within the same database. In this way we can open a file and use more than a table.

Actually when `open(DSN,"o",user,password)` is called Unicon allocates an `ISQLFile` object and initializes the structure fields in the following way:

- `hdbc` is related to the DSN specified in `open()`
- `hstmt` is related to `hdbc`

# Chapter 30

## Portable 2D and 3D Graphics

Two-dimensional graphics were originally added to Icon version 8 out of a desire to use Icon for software visualization. Visualization research called for rapid graphics prototyping and Icon is a rapid prototyping language. The facilities were successful enough to warrant painstaking porting (to OS/2 and then MS Windows) and documentation (Griswold wrote a larger book for the Icon graphics facilities than the Icon book) efforts. Two elaborate graphic user interface libraries (with interface builders) were developed, the first in Idol by Jon Lipp and Mary Cameron, and the second in Unicon by Robert Parlett. Unicon Version 11 introduced a powerful set of 3D graphics facilities, increasing the footprint of the graphics in the overall implementation.

This chapter describes the design and implementation internals of the 2D and 3D graphics facilities and their window system implementation. It is intended for persons extending the graphics facilities or porting Unicon to a new window system. This chapter is derived from Unicon Technical Report #5, by Clint Jeffery, Naomi Martinez and Jafar Al Gharaibeh.

Much of the code is devoted to hiding specific features of C graphics interfaces that were deemed overly complex or not worth the coding effort they entail. Other implementation techniques are motivated by portability concerns. The graphics interface described below has been implemented to various levels of completeness on the X Window System, Microsoft Windows, OS/2 Presentation Manager, (pre OS X) Macintosh, and Borland Graphics Interface platforms. Most of this discussion is relevant also for Icon Version 9; Unicon's graphics facilities include minor improvements.

### 30.1 Graphics Source Files Summary

Unicon's window facilities consist of several source files, all in the `src/runtime` directory unless otherwise noted. They are discussed in more detail later in this document.

**header files** – `h/graphics.h` contains structures and macros common across platforms. Each platform adds platform-specific elements to the common window structures defined in this file. In

addition, each platform gets its own header file, currently these consist of X Windows (h/xwin.h) and Microsoft Windows (h/mswin.h). Every platform defines several common macros in the window-system specific header file in addition to its window system specific structures and macros. The common macros are used to insert platform-dependent pieces into platform-independent code.

**Unicon functions** – fwindow.r contains the RTL (Run-Time Language) interface code used to define built-in graphics functions for the Unicon interpreter and compiler. For most functions, this consists of type checking and conversion code followed by calls to platform-dependent graphics functions. The platform dependent functions are described later in this document; fwindow.r is platform independent. You will generally modify it only if you are adding a new built-in function. For example, the Windows native functions are at the bottom of this file.

**internal support routines** – rwindow.r, rwinrsc.r, rgfxsys.r and rwinsys.r are basically C files with some window system dependencies but mostly consisting of code that is used on all systems. For example, rwindow.r is almost 100 kilobytes of portable source code related to Unicon's event model, attribute/value system, portable color names, GIF and JPEG image file support, palettes, fonts, patterns, spline curves and so forth.

**window-system specific files** – Each window system gets its own source files for C code, included by the various r\*.r files in the previous section. Currently these include rxwin.ri and rxrsc.ri for X Windows, and rmswin.ri for MS Windows. Each platform will implement one or more such r\*.ri files. In addition, common/xwindow.c contains so many X Window includes that it won't even compile under UNIX Sys V/386 R 3.2 if all of the Unicon includes are also present – so its a .c file instead of a .r file.

**tainted "regular" Unicon sources** – Many of the regular Unicon source files include code under `#ifdef Graphics` and/or one or more specific window system definitions such as `#ifdef XWindows` or `#ifdef MSWindows`. The tainted files that typically have to be edited for a new window system include h/grttin.h, h/features.h, h/rextens.h, h/rmacros.h, h/rproto.h, h/rstructs.h, and h/sys.h. Other files also contain Graphics code. This means that most of the system has to be recompiled with rtt and cc after Graphics is defined in h/define.h. You will also want to study the Graphics stuff in h/grttin.h since several profound macros are there. Also, any new types (such as structures) defined in your window system include files will need dummy declarations (of the form `typedef int foo;`) to be added there.

Under UNIX the window facilities are turned on at configuration time by typing

```
make X-Configure name=system
```

instead of the usual `make Configure` invocation. The X configuration modifies makefiles and defines the symbolic constant Graphics in h/define.h. If OpenGL libraries are detected, configuration enables them automatically. Similar but less automatic configuration handling is performed for other systems; for example, an alternate .bat file is used in place of os2.bat or turbo.bat.

### **Graphics #define-d symbols**

The primary, window-system-independent defined symbol that turns on window facilities is simply Graphics. Underneath this parent `#ifdef`, the symbol XWindows is meant to mark all X

Window code. Other window systems have a definition comparable to XWindows: for Microsoft Windows it is MSWindows. Turning on any of the platform specific graphics `#define` symbols turns on Graphics implicitly.

## 30.2 Structures Defined in `graphics.h`

The header file `graphics.h` defines a collection of C structures that contain pointers to other C structures from `graphics.h` as well as pointers into the window system library structures. The internals for the simplest Unicon window structure under X11 are depicted in Figure 1. The picture is slightly simpler under MS Windows, with no display state or related color or font management; on the other hand MS Windows maps the Unicon context onto a large set of resources, including pens, brushes, fonts and bitmaps.

Missing figure

Figure 1: Internal Structure of an Unicon Window Value

At the top, Unicon level, there is a simple structure called a *binding* that contains a pointer to a window state and a window context. Pointers to bindings are stored in the `FILE *` variable of the Unicon file structure, and most routines that deal with a window take a pointer to a binding as their first argument. Beneath this facade, several structures are accessed to perform operations on each window.

The window state holds the typical window information (size, text cursor location, an Unicon list of events waiting to be read) as well as a window system pointer to the actual window, a pointer to a backing pixmap (a "compatible device context" used to handle redraw requests), and a pointer to the display state.

The window context contains the current font, foreground, and background colors used in drawing/writing to the window. It also contains drawing style attributes such as the fill style. Contexts are separate from the window state so that they may be shared among windows. This is a big win, and Unicon programs tend to use it heavily, so in porting the window functions a central design issue must be the effective use of a comparable facility on other window systems, or emulating the context abstraction if necessary. Nevertheless, one might start out with `Couple()` and `Clone()` disabled and only allow one hardwired context associated with each window.

The display state contains whatever system resources (typically pointers or handles) that are shared among all the windows on a given display in the running program. For example, in X this includes the fonts, the colors, and a window system pointer for an internal Display structure required by all X library calls to denote the connection to the X server.

### 30.3 Platform Macros and Coding Conventions

Since the above structure is many layers deep and sometimes confusing, Unicon's graphics interface routines employ coding conventions to simplify things. In order to avoid many extra memory references in accessing fields in the multi-level structure, "standard" local variables are declared in most of the platform dependent interface routines in `rxwin.ri` and `rmswin.ri`. The macro `STDLOCALS(w)` declares local variables pointing to the most commonly used pieces of the window binding, and initializes them from the supplied argument; each window system header should define an appropriate `STDLOCALS(w)` macro. Under some window systems, such as MS Windows, `STDLOCALS(w)` allocates resources which must be freed before execution continues, in which case a corresponding `FREE_STDLOCALS(w)` macro is defined.

Some common standard locals are `wc`, `ws`, `stdwin`, and `stdpix`. While `wc`, and `ws` are pointers to structures copied from the window binding, `stdwin`, and `stdpix` are actual X (or MS Window) resources that are frequently supplied to the platform-dependent routines as arguments. Each window system will have its own standard locals. For example, MS Windows adds `stdwc` and `stdpix` since it uses a device context concept not found in X11.

In much of the platform-dependent source code, the window system calls are performed twice. This is because most platforms including X11 and MS Windows do not remember the contents of windows when they are reduced to iconic size or obscured behind other windows. When the window is once again exposed, it is sent a message to redraw itself. Unicon hides this entirely, and remembers the contents of the window explicitly in a window-sized bitmap of memory. The calling of platform graphics routines twice is so common that a set of macros is defined in `xwin.h` to facilitate it. The macros are named `RENDER2` through `RENDER6`, and each of them takes an Xlib function and then some number of arguments to pass that function, and then calls that function twice, once on the window and once on the bitmap.

Platforms that provide backing store may avoid this duplicated effort. In practice however it seems most window systems have redraw events even if they implement retained windows (for example, MGR [Uhler88]).

### 30.4 Window Manipulation in `rxwin.ri` and `rmswin.ri`

The platform-dependent calls in the Unicon run-time system can be categorized into several major areas:

- Window creation and destruction
- Low-level event processing
- Low-level text output operations

- Window and context attribute manipulation

### 30.4.1 Window Creation and Destruction

A graphics window is created when the Unicon program calls `open()` with file attribute "g". The window opening sequence consists of a call to `wopen()` to allocate appropriate Unicon structures for the window and evaluate any initial window attributes given in additional arguments to `open()`. After these attributes have been evaluated, platform resources such as fonts and colors are allocated and the window itself is instantiated. Under X, `wopen()` busy-waits until the window has received its first expose event, ensuring that no subsequent window operation takes place before the window has appeared onscreen.

A window is closed by a call to `wclose()`; this removes the on-screen window even if other bindings (Unicon window values) refer to it. A closed window remains in memory until all Unicon values that refer to it are closed. A call to `unbind()` removes a binding without necessarily closing the window.

### 30.4.2 Event Processing

The system software for each graphics platform has a huge number of different types of events. Unicon ignores most of them. Of the remainder, some are handled by the runtime system code in the .ri files implicitly, and some are explicitly passed on to the Unicon program.

Most native graphic systems require that applications be event-driven; they must be tightly I/O bound around the user's actions. The interaction between user and program must be handled at every instant by the program. Unicon, on the other hand, considers this event-driven model optional.

Making the event-driven model optional means that the Unicon interface must occasionally read and process events when the Unicon program itself is off in some other computation. In particular, keystrokes and mouse events must be stored until the user requests them, but exposure events and resizes must be processed immediately. The Unicon interpreter pauses at regular intervals in between its virtual machine instructions (the Unicon compiler emits polling code in its generated C code, so window system facilities are supported by the compiler as well) and polls the system for events that must be processed; this technique fails when no virtual machine instructions are executing, such as during garbage collections or when blocked on file I/O.

On some platforms such as X, this probably could be done using the platform event queue manipulation routines. Instead, the Unicon window interface maintains its own keystroke and mouse event queue from which the Unicon functions obtain their events. This additional queue makes the implementation more portable. Various window systems probably do not support queue manipulation to the extent or in the same way that X does. It also provides the programmer with a higher level event processing abstraction which has proven useful.

Window resizing is partly handled by the interface. The old contents of the window are retained in their original positions, but the program is informed of the resize so it can handle the resize in a more reasonable manner. As has already been noted exposure events are hidden entirely via the use of a backing pixmap with identical contents for each window. The pixmap starts out the same size as the window. It is resized whenever the window grows beyond one of its dimensions. It could be reduced whenever the window shrinks, but then part of the window contents would be lost whenever the user accidentally made the window smaller than intended.

The platform-dependent modules also contains tables of type stringint. These tables are supported by routines that map strings for various attributes and values to native window system integer constants. Binary search is employed. This approach is a crude but effective way to provide symbolic access "built-in" to the language without requiring include files. Additional tables mapping strings to integers are found in the platform independent source files.

### **30.4.3 Resource Management**

One of the most important tasks performed by platform-specific graphics functions is the management of resources, both the on-screen resources (windows) and the drawing context elements used by the window system in performing output.

### **30.4.4 Memory Management and r\*rsc.ri Files**

Memory management for internal window structures is independent of Unicon's standard memory management system. Xlib memory is allocated using malloc(2).

Most internal Unicon window structures could be allocated in Unicon's block region, but since they are acyclic and cannot contain any pointers to Unicon values, this would serve little purpose (Actually, it is probably the right thing to do, and will probably happen some day, but its just not in the cards right now unless you feel like messing with the garbage collector.). In addition when an incoming event is being processed it has to be matched up with the appropriate window state structure, so some of the window structures must be easily reached, not lost in the block region. The window interface structures are reference counted and freed when the reference count reaches 0.

### **30.4.5 Color Management**

Managing colors under X Windows is painful. In particular, if the same color is allocated twice the color table entry is shared (which is good) and that entry may only be freed once (which is bad). For this reason, every color allocated by Unicon is remembered and duplicate requests are identified and freed only once. In the general case it is impossible to detect when a particular color

is no longer being displayed, and so colors are only freed on window closure or when a window is cleared.

### **30.4.6 Font Management**

Unicon supports a portable font name syntax. Since the available fonts on systems vary widely, "interesting" code has been written to support these portable names on various X servers. Each window system may need to include heuristics to pick an appropriate font in the font allocation routine in the window system's `r*.ri` file.

## **30.5 External Image Files and Formats**

Reading and writing window contents to external files is accomplished by the routines `loadimage()` and `dumpimage()`, implemented in each platform's window system specific file, such as `rxwin.ri`. These routines take a window binding and a string filename and perform the I/O transfer. Presently, the file format is assumed to be indicated by the filename extension; this is likely to change. Ideally Unicon should tolerate different file formats more flexibly, inferring input file formats by reading the file header where possible, and running external conversion programs where appropriate.

GIF and JPEG files are self-identifying, so they are always recognized independent of name. They are checked in system-independent code before platform-specific image reading code is invoked.

## **30.6 Implementation of 3D Facilities**

In order to implement the 3D facilities, the Unicon runtime system was modified to support 2D and 3D windows. The Unicon runtime system is written in a custom superset dialect of C called RTL [Walker94]. The 3D facilities use the existing 2D facilities code for window creation and destruction, as well as handling keyboard and mouse input.

### **30.6.1 3D Facilities Requirements**

OpenGL 1.2 or later must be present on the system in order for Unicon's 3D graphics facilities to work. A check for this is performed in `wopengl()` which can be found in the file `ropengl.ri`. The requirement of OpenGL 1.2 is based on the fact that the function `glTexBind()`, which make the implementation of textures more efficient, is only available in OpenGL 1.2 and later.

Also needed for the Unicon 3D graphics facilities is a system that supports a true color visual with a depth buffer of 16 and a double buffer. The requirement of a depth buffer is a necessity to implement lighting. For lighting to work properly in OpenGL, a depth test must be performed,

hence the need of a depth buffer. A double buffer is needed to implement the list structure that is used to redraw a window. More information can be found on redrawing of windows in section 7.3.

### 30.6.2 Files

Several existing files contain extensions to support the Unicon 3D graphics facilities under `#ifdef Graphics3D`, including `data.r` (new runtime error codes), `fwindow.r` (new 3D functions), `rmem-mgt.r` (3D window display lists), `rxwin.ri` and `rmswin.ri` (modified `wopen()` and `wmap()` to support 3d mode), `rwindow.r` (new 3D attributes), and `graphics.h` (new 3D fields in canvas and context structures). Also a new file, `ropengl.ri` was added that contains the C helper functions for functions in `fwindow.r`, `rxwin.ri`, and `rwindow.r`.

### 30.6.3 Redrawing Windows

In the 2D graphics facilities, events that require the redrawing of a window are handled by using a pixmap. Instead of using a pixmap, for the Unicon 3D graphics facilities, a Unicon list of lists is created for each window opened in "gl" mode. This list of lists keeps track of all objects in a 3D graphics scene. This list is called `funclist` and is found in the `wstate` structure of a "gl" window. The individual lists contain the function name and the parameters of that function. Also placed on the list are attributes that affect the scene. These include `dim`, `linewidth`, `texcoord`, `texture`, `texmode`, and `fg`. When a window receives an event that requires redrawing, the window is cleared, all attributes are reset to the defaults, and the Unicon list of lists is traversed to redraw every object in the scene.

There are some functions and attributes that are not placed in the list. Instead they much either modify the list or call the list to redraw the scene. The function `EraseArea()`, not only clears the screen but also clears the contents of the list. The attributes `light0-light7`, `eye`, `eyeup`, `eyedir`, and `eyepos` use the list to redraw the window with the new attributes. So if the position of a light changes, the new lighting calculations are preformed and the scene is redraw. Besides these functions and attributes, every function or attribute available in the 3D graphics facilities is placed on this list. In is important to note that functions and attributes that have no effect in the 3D graphics facilities are not placed in this list.

### 30.6.4 Textures

In OpenGL, textures can be one, two, or three-dimensional and are represented as multi-dimensional arrays. In the Unicon 3D graphics facilities all texture are 2D dimensional, and represented as three-dimensional arrays. This array keeps track of the position and red, green, and blue components of each pixel in the texture image. When a texture image is specified in a Unicon program, the texture is converted from the Unicon internal representation of the image to a three-dimensional array. For most cases, this does not take a long time, but as a texture image gets

larger, the slower the application will run. Several measures have been taken in order to increase the efficiency of converting the texture image into an array. Since lighting and texturing are fairly expensive operations, especially if several lights are activated, these features are temporarily deactivated. Despite these efforts, converting a "g" window to a texture is still fairly expensive. Possible future work includes ways to speed up this process.

Instead of adding a texture to the list of lists as described in section 7.3, OpenGL's internal texture resources are used. OpenGL assigns to each texture a name. The names assigned to each texture in a Unicon scene are stored in `texname[]`, which can be found in a "gl" window's context. To ensure that a texture name is not reused, a call to `glGenTextures()` made which produces unused texture names. When a texture is applied to the scene, only the index of the array `texname[]` is stored in the list. When the list is traversed, a call to `glBindTexture()` is made which binds the texture to the subsequent objects in the scene. One problem of using this representation of textures is that it places an upper bound on the number of texture used. This is because `glGenTextures()` requires the number of texture names to generate. Also by using `glBindTexture()`, never deletes a texture from the texture resources, possibly using up all texture resources. Future work might look into when to delete a texture an ways to check when the texture resources have been used up.

### 30.6.5 Texture Coordinates

The primitives as mentioned in previous sections are cubes, tori, cylinders, disks, partial disks, points, lines, polygons, spheres, line segments, and filled polygons. Some of these primitives are drawn using different aspect of the OpenGL library, with some using the glu library. Points, lines, line segments, polygons, and filled polygons are drawing using `glBegin()`, `glEnd()`, and vertices in between the function calls. Cylinders, disks, partial disks, and spheres are implemented using the glu library. They are considered to be `gluQuadrics` objects. Finally cubes and tori are a composition of several polygons.

The texturing method used is influenced by the how the primitive is composed. For the primitives built using the OpenGL library, default texture coordinates are obtain much differently than those primitives built using the glu library. For those primitives built using `glBegin()` and `glEnd()`, `glTexGen()` is used to determine the default parameters when "texcoord=auto". In order to use this feature we must enable `GEN_S` and `GEN_T` with `glEnable()`. This generates texture coordinates for a 2D textures. The texture coordinates for a torus are obtained in the same ways.

Primitives built using the glu library, have texture coordinates associated with them. These texture coordinates can be obtained by calling `gluQuadricTexture()`. The use of the glu texture coordinates verses the OpenGL coordinates, is due to the fact that the glu texture coordinate look nicer. In order to use these texture coordinates instead of the ones specified by OpenGL, it is necessary to disable `GEN_S` and `GEN_T`. After the object has been drawn, `GEN_S` and `GEN_T` are turned back on.

A cube uses default texture coordinates that map the texture onto each of the faces of a cube. In

order to use these default coordinates, it is necessary to disable GEN\_S and GEN\_T, similar to glu objects.

## 30.7 Graphics Facilities Porting Reference

This section documents the window-system specific functions and macros that generally must be implemented in order to port Unicon's graphics facilities to a new window system. The list is compiled primarily by studying fwindow.r, rwindow.r, and the existing platforms.

A note on types: **w** is a window binding pointer (wbp), the top level Unicon "window" value. **i** is an integer, **s** is a string. **wsp** is the window state (a.k.a. canvas) pointer, and **wcp** is the window context pointer. A bool return value returns one of the C macro values Succeeded or Failed, instead of the usual C booleans 1 and 0.

---

### ANGLE(a)

Convert from radians into window system units. For example, under X these are 1/64 of a degree integer values.

---

### ARCHEIGHT(arc)

The height component of an XArc.

---

### ARCWIDTH(arc)

The width component of an XArc.

---

### ASCENT(w)

Returns the number of pixels above the baseline for the current font. Note that when Unicon writes text, the (x,y) coordinate gives the left edge of the character at its baseline; some window systems may need to translate our coordinates.

---

### int blimage(w, x, y, width, height, ch, s, len)

Draws a bi-level (i.e. monochrome, 1-bit-per-pixel) image; used in DrawImage() which draws bitmap data stored in Unicon strings.

---

### wcp clone\_context(w)

Allocate a new context, cloning attributes from w's context.

---

### COLTOX(w, i)

Return integer conversion from a 1-based text column to a pixel coordinate.

---

### copyArea(w1, w2, x, y, width, height, x2, y2)

Copies a rectangular block of pixels from w1 to w2.

---

### DESCENT(w)

Returns the number of pixels below the baseline for the current font.

#### **DISPLAYHEIGHT(w)**

Return w's display (screen) height in pixels.

#### **DISPLAYWIDTH(w)**

Return w's display width in pixels.

#### **bool do\_config(w, i)**

Performs move/resize operations after one or more attributes have been evaluated. Config is a word with two flags: the one bit indicates a move, the two bit indicates a resize. The desired sizes are in the window state pointer, e.g. w->window->width.

#### **drawarcs(w, thearcs, i)**

Draw i arcs on w, given in an array of XArc structures. Define an appropriate XArc structure for your window system; it must include fields x, y and width and height fields accessible through macros ARCWIDTH() and ARCHEIGHT(). Also, a starting angle angle1 and arc extent angle2, assigned through macros ANGLE(), EXTENT(), and FULLARC.

#### **drawlines(w, points, i)**

Draw i-1 connected lines, connecting the dots given in points.

#### **drawpoints(w, points, i)**

Draw i points.

#### **drawsegments(w, segs, i)**

Draw i disconnected line segments; define an Xsegment structure appropriate to your window system, consisting of fields x1, y1, x2, y2. This type definition requirement should be cleaned up someday.

#### **drawstring(w, x, y, s, s\_len)**

Draw string s at coordinate (x,y) on w. Note that y designates a baseline, not an upper-left corner, of the string.

#### **drawrectangles(w, rectangles, i)**

Draw i rectangles. Define an XRectangle structure appropriate to your window system.

#### **int dumpimage(w, s, x, y, width, height)**

Write an image of a rectangular area in w to file s. Returns Succeeded, Failed, or NoCvt if the platform doesn't support the requested format. Note that this is the "platform- dependent image writing function"; requests to write GIF or JPEG are handled outside of this function.

#### **eraseArea(w, x, y, width, height)**

Erase a rectangular area, that is, set it to the current background color. Compare with `fillrectangles()`.

---

**EXTENT(a)**

Convert from radians into window system units. Under `PresentationManager` it had to convert to units of  $1/65536$  of a circle along with a weird type conversion.

---

**fillarcs(w, arcs, i)**

Fill wedge-like arc sections (pie pieces). See `drawarcs()`.

---

**fillrectangles(w, rectangles, i)**

Fill *i* rectangles. See `drawrectangles()`.

---

**fillpolygon(w, points, i)**

Fill a polygon defined by *i* points. Connect first and last points if they are not the same.

---

**FHEIGHT(w)**

Returns the pixel height of the current font, hopefully `ASCENT + DESCENT`.

---

**free\_binding(w)**

Free binding associated with *w*. This gets rid of a binding that refers to *w*, without necessarily closing the window itself (other bindings may point to that window).

---

**free\_context(wc)**

Free window context *wc*.

---

**free\_mutable(w, i)**

Free mutable color index *i*.

---

**free\_window(ws)**

Free window canvas *ws*.

---

**freecolor(w, s)**

Free a color allocated on *w*'s display.

---

**FS\_SOLID**

Define this to be the window system's solid fill style symbol.

---

**FS\_STIPPLE**

Define this to be the window system's stippled fill style symbol.

---

**FULLARC**

Window-system value for a complete (360 degree) circle or arc.

---

**FWIDTH(w)**

Returns the pixel width of the widest character in the current font.

---

wsp getactivewindow()

Return a window state pointer to an active window, blocking until a window is active. Probably will be generalized to include a non-blocking variant. Returns NULL if no windows are opened.

---

getbg(w, s)

Returns (writes into s) the current background color.

---

getcanvas(w, s)

Returns (writes into s) the current canvas state.

---

getdefault(w, s\_prog, s\_opt, s)

Get any window system defaults for a program named s\_prog resource named s\_opt, write result in s.

---

getdisplay(w, s)

Write a string to s with the current display name.

---

getdrawop(w, s)

Return current drawing operation, one of various logical combinations of source and destination bits.

---

getfg(w, s)

Returns (writes into s) the current foreground color.

---

getfontnam(w, s)

Returns (writes into s) the current font. This interface may get changed since a portable font naming mechanism is to be installed. Name is presently always prefixed by "font=" (pretty stupid, huh); must be an artifact of merging window system ports, will be changed.

---

geticonic(w, s)

Return current window iconic state in s, could "iconify" or whatever. Obsolete (subsumed by canvas attribute, getcanvas()).

---

geticonpos(w, s)

Return icon's position to s, an encoded "x,y" format string.

---

int getimstr(w, x, y, width, height, paltbl, data)

Gets an image as a string. Used in GIF code.

---

getlinestyle(w, s)

Return current line style, one of solid, dashed, or striped.

---

`get_mutable_name(w, i)`

Returns the string color name currently associated with a mutable color.

---

`getpattern(w, s)`

Return current fill pattern in s.

---

`getpixel(w, x, y, long *rv)`

Assign RGB value for pixel (x,y) into \*rv.

---

`getpixel_init(w, struct imgmem *imem)`

Prepare to fetch pixel values from window, obtaining contents from server if necessary. This function does all the real work used by subsequent calls to `getpixel()`.

---

`getpointername(w, s)`

Write mouse pointer appearance, by name, to s.

---

`getpos(w)`

Update the window state's `posx` and `posy` fields with the current window position.

---

`getvisual(w, s)`

Write a string to s that explains what type of display w is on, e.g. "visual=x,y,z", where x is a class, y is the bits per pixel, and z is number of colormap entries available. This X-specific anachronism is likely to go away.

---

`HideCursor(wsp ws)`

Hide the text cursor on window state ws.

---

`ICONFILENAME(w)`

Produce char \* for window's icon image file name if there is one.

---

`ICONLABEL(w)`

Produce char \* for icon's title if there is one.

---

`isetbg(w, i)`

Set background color to mutable color table entry i. Mutable colors are not available on all display types.

---

`isetfg(w, i)`

Set foreground color to mutable color table entry i. Mutable colors are not available on all display types.

---

`ISICONIC(w)`

Return 1 if the window is presently minimized/iconic, 0 otherwise.

---

---

**ISFULLSCREEN(w)**

Return 1 if the window is presently maximized/fullscreen, 0 otherwise.

---

**ISNORMALWINDOW(w)**

Return 1 if the window is neither minimized nor maximized, 0 otherwise.

---

**LEADING(w)**

Return current integer leading, the number of pixels from line to line.

---

**LINEWIDTH(w)**

Return current integer line width used during drawing.

---

**lowerWindow(w)**

Lower the window to the bottom of the stack.

---

**mutable\_color(w, dptr dp, i, C\_integer \*result)**

Allocate a mutable color from color spec given by dp and i, placing result (a small negative integer) in \*result.

---

**nativecolor(w, s, r, g, b)**

Interpret a platform-specific color name s (define appropriately for your window system). Under X, we can do this only if there is a window.

---

**pollevent()**

Poll for available events on all opened displays. This is where the interpreter calls the window system interface. Return a -1 on an error, otherwise return count of how long before it should be polled (400).

---

**query\_pointer(w, XPoint \*xp)**

Produce mouse pointer location relative to w.

---

**query\_rootpointer(XPoint \*xp)**

Produce mouse pointer location relative to root window on default screen.

---

**raiseWindow(w)**

Raise the window to the top of the stack.

---

**bool readimage(w, s, x, y, int \*status)**

Read image from file s into w at (x,y). Status is 0 if everything was kosher, 1 if some colors weren't available but the image was read OK; if a major problem occurs it returns Failed. See loadimage() for the real action.

---

**rebind(w, w2)**

Assign w's context to that of w2.

---

---

**RECEIGHT(rec)**

The height component of an XRectangle. Gets "fixed up" (converted) into a Y2 value if necessary, in window system specific code.

---

**RECWIDTH(rec)**

The width component of an XRectangle. Gets "fixed up" (converted) into a X2 value if necessary, in window system specific code.

---

**RECX(rec)**

The x component of an XRectangle.

---

**RECY(rec)**

The y component of an XRectangle.

---

**ROWTOY(w, i)**

Return integer conversion from a 1-based text row to a pixel coordinate.

---

**SCREENDEPTH(w)**

Returns the number of bits per pixel.

---

**int setbg(w, s)**

Set the context background color to s. Returns Succeeded or Failed.

---

**setcanvas(w, s)**

Set canvas state to s, make it "iconic", "hidden" or whatever. A canvas value extension such as fullscreen would go here. Changes in canvas state are tantamount to destroying the old window, creating a new window (with appropriate size and style) and adjusting the pixmap size correspondingly. Much of the associated logic, however, might be located in the event handlers for related window system events.

---

**setclip(w)**

Set (enable) clipping on w from its context.

---

**setcursor(w, i)**

Turn text cursor on or off. Text cursor is off (invisible) by default.

---

**setDisplay(w, s)**

Set the display to use for this window; fails if the window is already open somewhere.

---

**setdrawop(w, s)**

Set drawing operation to one of various logical combinations of source and destination bits.

---

**int setfg(w, s)**

Set the context foreground color to *s*. Returns Succeeded or Failed.

---

`setfillstyle(w, s)`

Set fill style to solid, masked, or textured.

---

`bool setfont(w, char **s)`

Set the context font to *s*. This function first attempts to use the portable font naming mechanism; it resorts to the system font mechanism if the name is not in portable syntax.

---

`setgamma(w, gamma)`

Set the context's gamma correction factor.

---

`setgeometry(w, s)`

Set the window's size and/or position.

---

`setheight(w, i)`

Set window height to *i*, whether or not window is open yet.

---

`seticonicstate(w, s)`

Set window iconic state to *s*, it could be "iconify" or whatever. Obsolete; `setcanvas()` is more important.

---

`seticonimage(w, dptr d)`

Set window icon to *d*. Could be string filename or existing pixmap (i.e. another window's contents). Pixmap assignment no longer possible, so one could simplify this to just take a string parameter.

---

`seticonlabel(w, s)`

Set icon's string title to *s*.

---

`seticonpos(w, s)`

Move icon's position to *s*, an encoded "x,y" format string.

---

`setimage(w, s)`

Set an initial image for the window from file *s*. Only valid during `open()`.

---

`setleading(w, i)`

Set line spacing to *i* pixels from line to line. This includes font height and external leading, so *i* < fontheight means lines draw partly over preceding lines, *i* > fontheight means extra spacing.

---

`setlinestyle(w, s)`

Set line style to solid, dashed, or striped.

---

`setlinewidth(w, i)`

Set line width to *i*.

---

`set_mutable(w, i, s)`

Set mutable color index *i* to color *s*.

---

`SetPattern(w, s, s_len)`

Set fill pattern to bits given in *s*. Fill pattern is not used unless `fillstyle` attribute is changed to "patterned" or "opaquepatterned".

---

`SetPatternBits(w, width, bits, nbits)`

Set fill pattern to bits given in the array of integers named *bits*. Fill pattern is not used unless `fillstyle` attribute is changed to "patterned" or "opaquepatterned".

---

`setpointer(w, s)`

Set mouse pointer appearance to shape named *s*.

---

`setpos(w, s)`

Move window to *s*, a string encoded "(x,y)" thing.

---

`setwidth(w, i)`

Set window width to *i*, whether or not window is open yet.

---

`setwindowlabel(w, s)`

Set window's string title to *s*.

---

`ShowCursor(wsp ws)`

Show the text cursor on window state *ws*.

---

`int strimage(w, x, y, width, height, e, s, len)`

Draws a character-per-pixel image, used in `DrawImage()`. See `blimage()`.

---

`SysColor`

Define this type to be the window system's RGB color structure.

---

`TEXTWIDTH(w, s, s_len)`

Returns the integer text width of *s* using *w*'s current font.

---

`toggle_fgbg(w)`

Swap the foreground and background on *w*.

---

`unsetclip(w)`

Disable clipping on *w* from its context.

---

`UpdateCursorPos(wsp ws, wcp wc)`

Move the text cursor on window state *ws* and context *wc*.

---

walert(w, i)

Sounds an alert (beep). i is a volume; it can range between -100 and 100; 0 is normal.

---

warpPointer(w, x, y)

Warp the mouse location to (x,y).

---

wclose(w)

Closes window w. If there are other bindings that refer to the window, they are converted into pixmapes, i.e. the window disappears but the canvas is still there and can be written on and copied from.

---

wflush(w)

Flush output to window w; a no-op on some systems.

---

wgetq(w, dptr result)

Get an event from w's pending queue, put results in descriptor \*res. Returns -1 for an error, 1 for success (should fix this).

---

WINDOWLABEL(w)

Produce char \* for window's title if there is one.

---

FILE \*wopen(s, struct b\_list \*lp, dptr attrs, i, int \*err\_index, is\_3d)

Open window named s, with various attributes. This ought to be merged from various window system dependent files, but presently each one defines its own. Copy and modify from rxwin.ri or rmswin.ri. The return value is really a wbp, cast to a FILE \*.

---

wputc(c, w)

Draw character c on window w, interpret newlines, carriage returns, tabs, deletes, backspaces, and the bell.

---

wsync(w)

Synchronize server and client (a no-op on most systems).

---

xdis(w, s, s\_len)

Draw string s on window w, low-level.

---

XTOCOL(w, i)

Return integer conversion from a 0-based pixel coordinate to text column.

---

YTOROW(w, i)

Return integer conversion from a 0-based pixel coordinate to text row.

---

## 30.8 The X Implementation

The reference implementation of Unicon's graphics facilities is written in terms of Xlib, the lower-level X Window C interface [Nye88]. It does not use the X resource manager. The end result of these two facts is that the implementation is relatively visible: the semantics are expressed fairly directly in the source code. Although it is necessary to understand the semantics of the underlying X routines, hidden behavior has been minimized.

Unicon does not rely on the X Toolkit Intrinsics (Xt) or any higher level widget set such as Motif. This guarantees that Unicon will compile and run on any X11 platform. Unicon programs implement their own look and feel, which may or may not be consistent with the other applications on a given X workstation. The Unicon Program Library includes routines that implement user interface components with an appearance that is similar to Motif.

The X implementation employs the XPM X pixmap library if it is available; XPM is a file format and API for storing color images in external files [LeHors96]. XPM provides color facilities analogous to the built-in X black-and-white bitmap routines. In addition to the image formats native to each platform, Unicon also supports GIF and JPEG as portable image file formats.

## 30.9 The MS Windows Implementation

The Microsoft Windows implementation of Unicon is written using Win32, the lower-level 32-bit Windows API. It does not use the Microsoft Foundation Classes. This makes it easier to build with different C compilers, and easier to port to different Windows implementations, such as Windows CE.

### 30.9.1 Installing, Configuring, and Compiling the Source Code

Building Unicon for Windows requires Mingw32 GCC. We hope to add Cygwin GCC support in the future. The sources may also build with modest revision under MS Visual C++. You are encouraged to try building using other compilers, and send Unicon Project your configuration files. You will need a robust Win32 platform to compile these sources; the build scripts and "make" process tend to fail on older versions of Windows.

1. Unpack the sources.

Unpack uni.zip in such a way that it preserves its subdirectory structure. Unzip.exe is recommended rather than WinZip. See Icon Project Document 243 [ipd243] for a picture of the directory hierarchy. In particular, there should be a BIN directory along with the SRC directory under the unicon/ directory.

2. Configure the sources.

Run "make W-Configure-GCC" (or "make W-Configure" under MSVC) to configure your

sources to build wiconx and wicont, the Unicon virtual machine interpreter, and the Unicon byte-code compiler, with graphics facilities enabled.

### 3. Compile to make executables.

Run "make Unicon" to build the currently-configured binary set. It is worth discussing why I provide makefiles instead of a project file for use in the Visual C++ IDE. The reason is that the source files for the Unicon virtual machine interpreter (generically called iconx; wiconx.exe in this case) are written in an extended dialect of ANSI C called RTL [ipd261]. Files in this language have the extension .r instead of .c and .ri instead of .h. During compilation, a program called rtt (the run time translator) translates .r\* files into .c files. If someone wants to show me how to insert this step into the Visual C++ IDE build process, I would be happy to use their IDE. You can write project files for the other C programs that make up the Unicon system, but most modifications to the language are changes to the interpreter.

#### Notes on the MS Windows internal functions

The functions documented here are those most likely to be involved in projects to add features to Windows Unicon.

---

### **handle\_child(w, UINT msg, WPARAM wp, LPARAM lp)**

This procedure handles messages from child window controls such as buttons. In many cases, this enqueues an event on the Unicon window.

---

### **int playmedia(w, char \*s)**

This crude function will call one of several multimedia functions depending on whether s is the name of a multimedia file (.wav, .mid, .rmi are supported) or an MCI command string.

---

### **int getselection(w, char \*s)**

Return the current contents of the clipboard text. The design of this and setselection() need to be broadened a bit to support images.

---

### **int setselection(w, char \*s)**

Set the clipboard text to s.

# Chapter 31

## The Uniconc Optimizing Unicon Compiler

Author: Michael Wilder

This chapter describes the design and development of a set of extensions to the Iconc optimizing compiler and to the Unicon translator to support each other. Taken together, these extensions form an optimizing compiler for (almost all of) Unicon. The work was originally presented in [Wilder06] and appears here in a revised form by permission of the author.

### 31.1 Overview

The Unicon translator translates Unicon programs into an extended dialect of Icon proper. The Icon translator (Iconc), executive (Iconx), and run-time library have been modified to accommodate various extensions that have been made since the Icon language was “frozen” in the 1990’s. Unicon programs are interpreted using the updated versions of Iconx and the run-time library.

Lexical, syntactic, and semantic analysis of Unicon is described in Chapter 27. Selected summary information is presented here to provide a context for the description of the modifications made to the Unicon translator to support iconc.

In the area of syntax analysis, it is worth noting that the parse tree produced by Unicon is a hybrid composed of generic treenodes and nodes representing semantically rich units such as classes and methods. Actions associated with rules in the Unicon grammar create this hybrid parse tree. Many of the transformations required to translate Unicon into Icon are performed during this phase.

Semantic analysis of a Unicon unit begins with a parse tree traversal to identify and perform name mangling on symbols associated with packages and classes. Transitive closure of the superclass graph associated with any classes is performed, followed immediately by inheritance resolution for classes. The specification of any package or classes encountered are then written out to a database for subsequent use. Methods associated with objects inserted into the parse tree during syntactic analysis are invoked during semantic analysis to accomplish these tasks.

Generating the Icon code for a given Unicon unit is accomplished by a traversal of the parse tree for that unit. Methods associated with objects inserted into the parse tree during syntactic analysis are again used to accomplish code generation. Readability of the final product is facilitated by minor formatting calisthenics performed during this phase.

## 31.2 Uniconc Organization

The organization of the Uniconc compiler is somewhat atypical. The organizational peculiarities of Uniconc and the tradeoffs associated with these peculiarities are described in the sections contained in this chapter.

Uniconc is composed of three subsystems: a modified version of the Unicon translator (Unicon<sup>Δ</sup>), a modified version of the Iconc optimizing compiler (Iconc<sup>Δ</sup>), and a modified version of the Unicon run-time library (RTL<sup>Δ</sup>). The purpose of each of these subsystems is largely the same as its predecessor, but each has been modified to some degree in order to accomplish the compilation of Unicon programs. The Unicon<sup>Δ</sup> subsystem translates programs presented in the Unicon programming language into the Icon programming language. The Iconc<sup>Δ</sup> subsystem translates programs presented in the Icon programming language into the C programming language. The RTL<sup>Δ</sup> serves to provide functionality commonly used in Unicon and Icon programs to a program executing on a given platform.

The topology of Uniconc as depicted in Figure 31.1 reveals that Uniconc shares some similarities with most traditional compilers while remaining fairly unique. There are three source languages involved in Uniconc. There are effectively four levels of intermediate code in Uniconc. There are two distinct phases of analysis and two distinct phases of synthesis in Uniconc.

## 31.3 Design Considerations

Uniconc is designed to facilitate experimentation. At the outset of this project the decision was made to retain and modify the Unicon translator rather than eliminate it by extending the syntax analyzer for Iconc to include Unicon constructs. This route was the shortest path to achieving the compilation of Unicon programs. More importantly, this decision endowed Uniconc with attributes that make it a useful tool for conducting code transformation experiments.

Intermediate code is produced by Uniconc at four points during the compilation process. Transformations performed in the semantic analysis phase of Unicon<sup>Δ</sup> produce intermediate code that is subsequently transformed by the optimization phase of Unicon<sup>Δ</sup> to produce Icon code acceptable to Iconc<sup>Δ</sup>. The Icon code produced by Unicon<sup>Δ</sup> is effectively another level of intermediate code. Transformations performed in the semantic analysis phase of Iconc<sup>Δ</sup> produce intermediate code that is subsequently transformed by the optimization phase of Iconc<sup>Δ</sup> before producing C code that

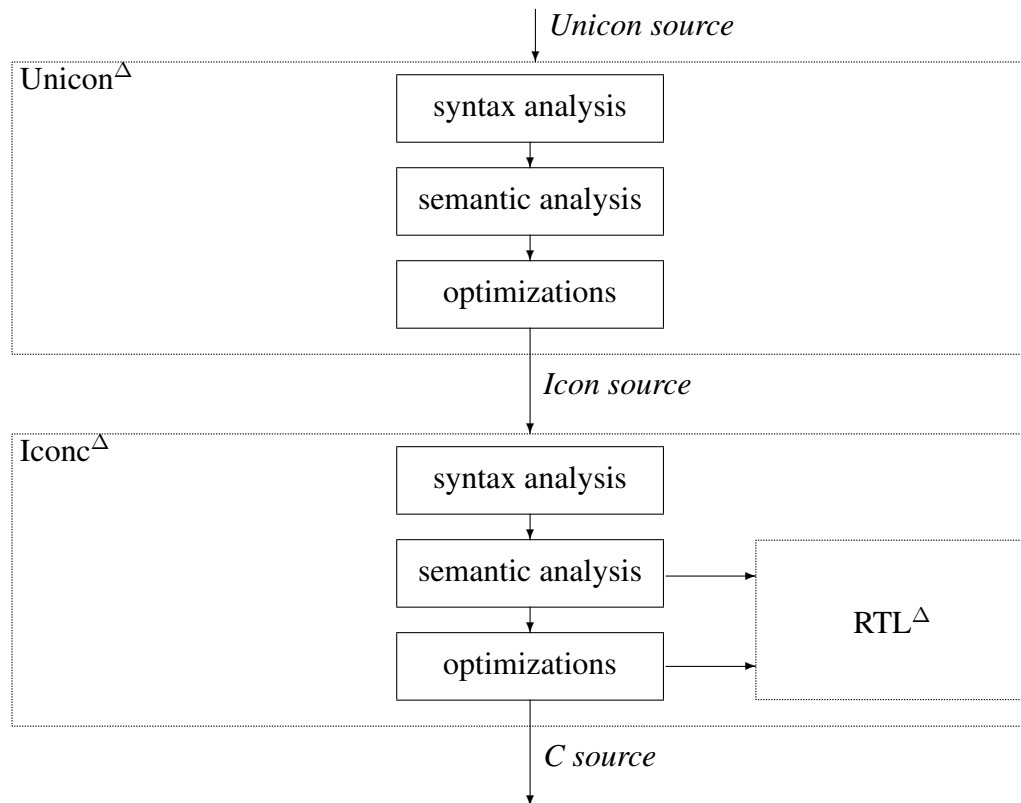

Figure 31.1: Uniconc Topology

is compiled by the host C compiler of a given system. The C code produced by Iconc<sup>Δ</sup> is effectively another level of intermediate code that is acted upon by the host C compiler. Each of these levels of intermediate code provides a waypoint at which the overall progress of a code transformation experiment can be evaluated. These waypoints also enable the design of code transformation experiments that span one or many levels of intermediate code. The transparency provided by these waypoints decreases the turnaround time for code transformation experiments and thereby increases the time that experimenters can devote to the design and analysis of transformations.

Early experiments with Iconc revealed many impressive features that were clearly of significant value. The decision not to implement a new syntax analyzer for Iconc<sup>Δ</sup> also greatly reduced the number of modifications that were required to produce Iconc<sup>Δ</sup> from Iconc, and thereby reduced the likelihood of introducing errors into a formidable tool. This same decision increased the number of modifications that were required to produce Unicon<sup>Δ</sup> from Unicon. Experience has shown, however, that the expressivity and pliability of the Unicon programming language make Unicon<sup>Δ</sup> a great place to introduce modifications.

Time, in its varied disguises, is ever a design consideration. During the design of Uniconc, a primary focus was the speed of compiled code. Early efforts in compiling Unicon programs during this project produced unsatisfactory results in this area. The speedup of code compiled

by Uniconc was gradually improved by performing code transformation experiments with Uniconc spanning single and multiple segments of intermediate code. The time required to complete code transformation experiments in Uniconc was itself also gradually reduced, but never at the expense of speedup in compiled code. The Uniconc compiler presented in this chapter is the result of many code transformation experiments conducted with earlier versions of Uniconc.

## 31.4 Translation Model

Programming language translation is the heart of any compilation system. Code transformations must be chosen carefully in order to accomplish translation that preserves the semantics of programmer input while simultaneously producing the best possible mapping to target code in terms of space-time constraints. The object-oriented Unicon programming language presents many challenges when translating into the procedural Icon programming language. Inheritance mechanisms in the Unicon programming language present particularly acute challenges when translating into the Icon programming language. Namespaces added by the Unicon programming language to provide encapsulation mechanisms also require particular care to ensure that the integrity of a namespace is not violated when translating into a procedural programming language such as Icon. The Unicon programming language has always been a VM-based interpreted language until the advent of Uniconc. Symbol resolution responsibilities that were performed at run-time by the Unicon interpreter require compile-time code transformations and symbol table manipulations that were not previously performed. The goal-directed nature of the Unicon and Icon programming languages poses particularly challenging problems when translating into an imperative programming language such as C. The intricacies involved in translating Icon into C were fortunately solved by the creators of Iconc.

The topology of Uniconc predicates a translation environment that differs from most compilers. Because the ultimate target language of Uniconc is C, traditional code transformational considerations relating to specifics of the target architecture are not a primary concern. This is simultaneously an advantage and a limitation. The peculiarity of generating intermediate code at effectively four places in three forms during the Uniconc compilation process places added emphasis on the order of application of code transformations in Uniconc, and likewise permits experimentation with transformations that span multiple forms (or segments) of intermediate code.

Many of the code transformations that occur during the compilation of a Unicon program by Uniconc are *simple* transformations that are applied within a single segment of intermediate code. Code transformations that are applied across multiple segments of intermediate code in Uniconc are referred to as *compound* or *inter-segment* transformations. The cumulative effect of an inter-segment transformation in Uniconc depends upon a sequence of subtransformations applied at multiple segments. This phenomenon is referred to as *inter-segment transformational dependency* in Uniconc. Many examples of simple code transformations appear throughout the remainder of this

chapter. An example of a compound code transformation and the particular set of inter-segment transformational dependencies it contains is detailed in Section 31.7.1.

Inter-segment transformations are inherently risky and require extensive experimentation. Care must be taken to ensure that the sequence of subtransformations applied by an inter-segment transformation do not produce side effects that nullify or otherwise dilute the efficacy of other transformations. Analysis of the results produced by an inter-segment transformation can be particularly delicate and time consuming because the correctness of code is potentially affected at multiple points in the translation stream.

## 31.5 The UNICON<sup>Δ</sup> Subsystem

The Unicon<sup>Δ</sup> subsystem of Uniconc is composed of three major phases as depicted in Figure 31.1. Each of these phases is presented in a separate section in this chapter in order to enumerate the major modifications that were necessary to these phases, and to illuminate the differences between Unicon<sup>Δ</sup> and Unicon.

### 31.5.1 Syntax Analysis

A command-line switch (-C) was added that permits the Uniconc user to indicate whether the Unicon source code is to be compiled or interpreted. This facility allows Uniconc to generate targets that are interpreted by Iconx or targets that run natively on a specific platform. The behavior of the Unicon<sup>Δ</sup> syntax analyzer is vastly different if the input source is intended to be compiled. This divergence of behavior is necessary because symbol resolution responsibilities that were performed at run-time by the Unicon interpreter require compile-time code transformations and symbol table manipulations when producing compiled targets. Semantic actions associated with productions in the Unicon grammar were modified to provide distinct functionality when Uniconc is used to generate compiled targets. Multiple code transformations occur during the Unicon<sup>Δ</sup> syntax analysis phase in the event that Uniconc is being used to produce a compiled result. The remainder of this section describes areas where the behavior of the Unicon<sup>Δ</sup> syntax analyzer diverges from that of the Unicon syntax analyzer when producing native versus VM-hosted targets.

The Icon programming language contains a grammatic construct that allows programmers to incorporate library procedures in user-level code. The Icon expression

```
link strings, graphics
```

directs that the procedures in the strings and graphics modules be made available to the Icon source currently being translated. The Unicon programming language inherits this construct from Icon, and adds a similar grammatic construct known as *packages*. The following Unicon expressions

```
package lang
import gui, cog
```

direct that the classes, declarations, and procedures found in the Unicon source currently being translated be made part of the lang package, and that the classes, declarations, and procedures found in the gui and cog packages be accessible in a syntactically convenient fashion by the Unicon source currently being translated. The Unicon expression

```
package f00
```

creates or adds to a namespace f00, whereas the following expression

```
import f00
```

permits access to the symbols previously defined in the f00 namespace. The Iconc<sup>Δ</sup> parser was not modified to accommodate these new Unicon constructs. Uniconc compensates for these constructs by identifying each link or import target in a compilation and parsing it exactly once. Each new link or import target encountered in a file that is itself a link or import target is also parsed. The resolution and parsing of link and import targets continues until all targets have been parsed once. This problem is solved by defining three tables in Unicon<sup>Δ</sup> called iconc\_links, iconc\_imports, and iconc\_parsed. Each time that a link or import expression is encountered during the parsing of a Unicon source file, Uniconc resolves the targets associated with the expression. Each target that is not already a member of the iconc\_parsed table is added to the iconc\_links or iconc\_imports table. After all input files specified on the Uniconc command-line are parsed, all members of the iconc\_links and iconc\_imports tables are themselves removed from their respective table, parsed, and added to the iconc\_parsed table. This continues until there are no members remaining in the iconc\_links and iconc\_imports tables. Handling the package and import constructs introduced by Unicon in this fashion permits the compile-time symbol resolution required by Iconc<sup>Δ</sup> to perform type inferencing without making any modifications to Iconc<sup>Δ</sup>.

Actions associated with productions for invocations in the Unicon grammar have been modified in order to perform code transformations as the parse tree for a Unicon source file is being populated. Different code transformations are performed depending upon the nature of the invocation encountered. The primary motivation for performing these code transformations is to reduce complex expressions in order to simplify vector table resolution in the Iconc<sup>Δ</sup> subsystem at compile-time. Rules for invocations appearing in the Unicon programming language grammar are shown in Figure 31.2. The expr11 nonterminal appearing in Figure 31.2 can produce many grammatic constructs, including other invocations. The expr11 nonterminal permits Unicon programs to contain arbitrarily complex expressions that describe the entity containing the procedure or method that is to be invoked. A sampling of invocations expressed in the Unicon programming language and the corresponding transformations performed by Uniconc on these invocations appears in Figure 31.3.

Consideration of Figure 31.3 reveals the nature of the transformations performed for invocations. A sequence of transformations are applied to each expression corresponding to an expr11 until the expression is reduced to an l-value held in a temporary Unicon variable. The types of

```

expr11 : ...
| expr11 LPAREN exprlist RPAREN {
    $$ := SimpleInvocation($1,$2,$3,$4);
    };
| expr11 DOLLAR INITIALLY LPAREN exprlist RPAREN {
    $$ := InvocationNodeShim($1,$2,$3,$4,$5,$6)
    };
| expr11 DOLLAR IDENT LPAREN exprlist RPAREN {
    $$ := InvocationNodeShim($1,$2,$3,$4,$5,$6)
    };
| expr11 DOLLAR IDENT DOT INITIALLY LPAREN exprlist RPAREN {
    $$ := InvocationNodeShim($1,$2,$3,$4,$5,$6,$7,$8)
    };
| expr11 DOLLAR IDENT DOT IDENT LPAREN exprlist RPAREN {
    $$ := InvocationNodeShim($1,$2,$3,$4,$5,$6,$7,$8)
    };

```

Figure 31.2: Invocations in the Unicon Grammar

```

x.peek().uncouple(y)  $\mapsto_1$ 
    (__1 := x.peek(x)) & __1.uncouple(__1,y);

(\n).g.k.get(23)  $\mapsto_2$ 
    ((__5 := (__4 := (\n).g) & __4.k) & __5.get(23));

self$buf.initially()  $\mapsto_3$ 
    (self) & (buf__oprec.initially(self));

(\f)$buf.initially()  $\mapsto_4$ 
    \ (f) & (buf__oprec.initially(f));

every (!a)$buf.initially()  $\mapsto_5$ 
    every ((__2:=(!a))) & (buf__oprec.initially(__2));

```

Figure 31.3: Sample Uniconc Invocation Transformations

l-values held in temporary variables are examined during the semantic analysis phase of Iconc<sup>Δ</sup> to determine whether further transformations are required in order to reproduce the semantics of the original invocation. In transformation  $\mapsto_2$  depicted in Figure 31.3, the type of the l-value `__5` must be ascertained in order to determine whether or not the invocation of `get` is the invocation of a field or a method. If the type of the l-value `__5` is not an instance of a class, no subsequent transformations are required to convey the semantics of the original invocation. In the event that the type of the l-value `__5` is an instance of a class, another transformation must be applied to the invocation in order to add the implicit “self” parameter when invoking the method `get` so that proper state of the class instance `__5` will be maintained and semantic closure can be attained. If `__5` is an instance of a class, the transformation depicted in Figure 31.3 is part of a compound or inter-segment transformation, and the insertion of the implicit self argument to attain semantic closure satisfies the inter-segment transformational dependency introduced by the initial transformation depicted in Figure 31.3.

The remaining transformations depicted in Figure 31.3 are simple transformations. In each of these transformations, enough information has been gleaned during the syntax analysis phase of Unicon<sup>Δ</sup> to unambiguously determine a single transformation that attains semantic closure with the original invocation. In the case of the invocation of a superclass method, as depicted in transformations  $\mapsto_3$ ,  $\mapsto_4$ , and  $\mapsto_5$  of Figure 31.3, transformations in Unicon<sup>Δ</sup> must discard the `$` operator because it is an extension of Icon proper. Earlier versions of Uniconc deferred method resolution until run-time. As experimentation with code transformations in Uniconc progressed, increasing subsets of functionality were added to the compiler and this methodology was discarded where possible in order to produce more efficient run-time behavior of compiled programs. In the rare event that the resolution of a method cannot be accomplished unambiguously at compile-time, Iconc<sup>Δ</sup> generates code in the form of a C switch statement to achieve resolution of a method at a given code point at run-time.

Actions associated with productions for field references in the Unicon grammar have been modified in order to perform code transformations as the parse tree for a Unicon source file is being populated. Different code transformations are performed depending upon the nature of the field reference encountered. Because a field reference in the Unicon programming language can be produced by the `expr11` nonterminal in the Unicon grammar, chains of field references are reduced to l-values held in temporary Unicon variables. As is the case with method invocations, these l-values are examined during the semantic analysis phase of Iconc<sup>Δ</sup> in order to ascertain the type of the entity to which a field reference is being made. The reductions performed by the code transformations applied to field references improve the quality of the code generated by Iconc<sup>Δ</sup> by reducing the work necessary to unambiguously determine the parent record or class containing a given named field.

The reductions performed by the code transformations applied to field references also improve the efficiency of compiled targets by ensuring that field references are not unnecessarily evaluated when inserting an implicit “self” argument in an invocation that has a field-reference as a

constituent `expr11`. In the following code snippet

```
x := r.o.m(23)
```

the implicit “self” argument that should be added to this invocation is `r.o`. A transformation applied producing this result

```
x := r.o.m(r.o,23)
```

would generate a superfluous second evaluation of `r.o`. A transformation that reduces the expression to an l-value before inserting the implicit argument produces

```
x := ((__1 := r.o) & __1.m(__1,23));
```

thereby saving the evaluation of a field reference at run-time. A fundamental problem solved by expression reduction in this case is revealed when attempting to determine the primary nature of `r.o`. In the example depicted above, if `r.o` is not an instance of a class, no transformation is required to achieve semantic closure. Determining whether `r.o` is an instance of a class is occasionally problematic in `UniconΔ`. In such cases, `UniconΔ` will produce a transformation of the form

```
x := ((__1 := r.o) & __1.m(23));
```

and defer resolution of the type of `r.o` until after type inferencing is performed during the semantic analysis phase of `IconcΔ`. If type inferencing reveals that `__1` (and thereby `r.o`) is an instance of a class, semantic closure of the compound transformation initiated in `UniconΔ` will be achieved by inserting the implicit `__1` as the first argument in the invocation of `m`.

### 31.5.2 Semantic Analysis

The semantic analysis phase of the current version of `UniconΔ` contains only minor modifications to accommodate `Uniconc`. Earlier versions of `Uniconc` contained extensive modifications to the semantic analysis phase of `UniconΔ`. Most of the modifications that were present in the `UniconΔ` semantic analysis phase of these earlier versions of `Uniconc` were mothballed after a system was devised to distinguish between class instances and record instances in `IconcΔ`. Before this system was devised, a separate pass over the parse tree during the semantic analysis phase of `UniconΔ` was necessary in order to attempt to disambiguate invocations and field references. The results produced by this additional pass were not of the same caliber that are currently achieved by deferring disambiguation until after type inferencing is performed during the semantic analysis phase of `IconcΔ`. The system devised to distinguish between class instances and record instances in `IconcΔ` is described in Section 31.6.1, and is employed in an optimization described in Chapter 31.7.

During the semantic analysis phase of `UniconΔ`, the parse tree is pruned of all nodes corresponding to package and import expressions. This pruning is necessary because `IconcΔ` has no knowledge of these grammatic constructs. The parse tree is also pruned of nodes corresponding

to link expressions because Unicon<sup>Δ</sup> handles all such expressions for compiled targets in order to resolve any package or import expressions that may be present within a file that is itself the target of a link expression. Checks are performed during this pruning to ensure that all package, import, and link expressions have been correctly resolved.

### 31.5.3 Code Generation

Minor modifications to the code generation phase of Unicon<sup>Δ</sup> were made in order to remove tail recursion from Unicon procedures that are recursively invoked while emitting generated Icon code. These modifications were made after exhausting space resources during the code generation phase of Unicon<sup>Δ</sup> on some computational platforms. These modifications are active whether a given target is to be interpreted or compiled.

Transformations are applied to Icon code generated by the Unicon<sup>Δ</sup> code generation phase in order to produce Icon code that decreases the number of field references required to accomplish the invocation of a Unicon method. This series of transformations is detailed in Section 31.7.1. The series of transformations performed at this point fundamentally modifies the representation of Unicon programming language class instances in Icon code generated by Unicon<sup>Δ</sup> and are therefore only performed for targets that are to be compiled. These transformations are accomplished in a separate post-processing pass over the Icon code generated by Unicon<sup>Δ</sup>. This additional pass imparts visibility into the transformational mappings produced, thereby reducing the amount of time required to analyze the results of code transformation experiments performed at this point. As experiments with this series of transformations progresses, they may become part of the Unicon<sup>Δ</sup> code generator proper and not require a separate pass over the Icon code generated by Unicon<sup>Δ</sup>.

## 31.6 The ICONC<sup>Δ</sup> Subsystem

The Iconc<sup>Δ</sup> subsystem of Uniconc is composed of three major phases as depicted in Figure 31.1. Each of these phases is presented in a separate section in this chapter in order to enumerate the major modifications that were necessary to these phases, and to illuminate the differences between Iconc<sup>Δ</sup> and Iconc.

### 31.6.1 Syntax Analysis

Record types are a primary vehicle for data abstraction in the Icon programming language. The Unicon programming language extends the notion of a record type by permitting users to declare and instantiate classes. Classes in Unicon are ultimately represented as Icon records before being interpreted or compiled. In certain cases it is very important to be able to differentiate between Icon records that represent Unicon classes and Icon records that represent Icon records. Invocations, as described in Section 31.5.1, are an example of this necessity. Classes in Unicon have

```

record class1__state(...)
record class1__methods(...)
global class1__oprec := class1__methods(...)

```

Figure 31.4: Simplified Unicon Class Representation

fundamentally different semantics than records in Icon. When it is impossible to differentiate between records that represent classes and records that represent records, information and therefore code transformational leverage are lost. In such a case, the designer of code transformations must choose to endow records with the same semantic properties as classes, to demote classes to the semantic equivalent of records, or to defer differentiation until run-time. None of these choices is particularly appealing.

It was recognized early on during the course of this project that the information lost by representing classes as records was information that had to be reclaimed. It was also recognized that requiring the type inferencing phase of Iconc<sup>Δ</sup> to perform significantly more computation or to consume more space as a result of this reclamation was not an option. Multiple experiments were performed before settling on an approach that balances the performance requirements of compiled code with the performance requirements of compiling code.

Each Unicon class is translated into a pair of Icon record declarations. These declarations contain a unique signature that can be detected at compile-time. A complete example of the Icon code produced for a Unicon class is shown in an appendix in [Wilder06]. A simplified representation of the Icon code produced for a Unicon class is depicted in Figure 31.4. Referring to this simplified representation reveals that a Unicon class named `class1` is translated into a pair of Icon record declarations. The record `class1__state` contains all of the data members associated with an instance of any `class1`, and the singleton instance of `class1__methods` called `class1__oprec` contains the operations shared by any `class1` instances. It should be noted that this is a simplification for the sake of discussing the method that was devised to distinguish between record instances and class instances during the compilation of a Unicon program. The actual representation of Unicon classes is transformed extensively by a post-processor in order to reduce the time required to perform a method invocation in Unicon programs compiled by Uniconc, and to reduce the space consumed by a class instance in Unicon programs compiled by Uniconc.

During the syntax analysis phase of Iconc<sup>Δ</sup>, each record declaration is added to a list of record entries of type `struct_rentry` detailing the record types that are present in a program. Each global entity detected by Iconc<sup>Δ</sup> is ascribed a set of attributes or flags that denote the nature of said entity. In the case of a record declaration, the flag `F_Record` is ascribed. Iconc<sup>Δ</sup> has been modified to add another attribute, called `F_Object`, that is ascribed in the event that a record declaration conforms to the unique signature indicating that it is the representation of a class instance. This attribute is checked during the semantic analysis and code generation phases of Iconc<sup>Δ</sup> in order to perform transformations that increase the efficiency of compiled code.

```

dbcol := ["col_1", "col_2"]
ctor := constructor("dbrow", dbcol[1], dbcol[2])
every i := 1 to *dbrows do {
    r := ctor(dbrows[i][1], dbrows[i][2])
    write("row: ", i, " col[1]: ", r.col_1, "col[2]: ", r.col_2)
}

```

Figure 31.5: Dynamic Records in Unicon

Further modifications to  $\text{Iconc}^\Delta$  have been made in order to reclaim the semantics of classes. During the syntax analysis phase,  $\text{Iconc}^\Delta$  detects operations records ( $\text{xxx\_oprec}$ ) instances and creates a vector table (vtbl) corresponding to each operation record instance encountered. These vtbls are accessed during the semantic analysis and code generation phases of  $\text{Iconc}^\Delta$  in order to reduce the number of field references required to perform a method invocation in compiled Unicon programs. Vector tables are logical wrappers that encapsulate global entries of type `struct gentry` in  $\text{Iconc}^\Delta$  and provide an interface for membership queries. Each vtbl is a lightweight construct requiring the space of two compile-time pointers.

The Unicon programming language extends the notion of a record type by permitting the instantiation of records whose form is not known until run-time. This language feature known as *dynamic records* is illustrated in Figure 31.5.

This language feature is based upon and exploits run-time information for which there exists no compile-time analog. Uniconc makes a limited effort to determine the number of dynamic records that may be instantiated at run-time. It is necessary for  $\text{Iconc}^\Delta$  to know the number of record types that may be instantiated at run-time in order to efficiently perform type inferencing during the semantic analysis phase. The design of  $\text{Iconc}^\Delta$  predicates that the number of types be known and fixed before type inferencing is performed. The syntax analysis phase of  $\text{Iconc}^\Delta$  has been modified to detect invocations of the constructor function and to create new record entries of the form `struct gentry`. Each `struct gentry` created contains the type name of the record and the name and number of the record fields when it is possible to determine this information at compile-time. The number of dynamic records encountered during syntax analysis is tabulated, and this information is used by  $\text{Iconc}^\Delta$  to perform type inferencing. The starting index of dynamic records is embedded in the code generated for a compiled Unicon program. This information embedded in the generated code is used to synchronize the  $\text{RTL}^\Delta$  with the compiled program in order to ensure that the  $\text{RTL}^\Delta$  does not assign record numbers to dynamic records in the constructor function that collide with record numbers used for non-dynamic records in a given program. The  $\text{RTL}^\Delta$  has been modified in order to permit the instantiation of dynamic records at run-time in compiled Unicon code. Empirical evidence suggests that the technique to avoid record number collisions at run-time in compiled Unicon programs is effective.

```

case N_Invok:
    /*
     * General invocation.
     */
    infer_nd(Tree1(n)); /* thing being invoked */

    if (Tree1(n)->n_type == N_Field && fldref_is_class(Tree1(n))) {
        methodinvok_add_implicit_self(n);
    }

    /*
     * Perform type inference on all the arguments and copy the
     * results into the argument type array.
     */
    sav_argtyp = arg_typs;
    sav_nargs = num_args;

```

Figure 31.6: Examining Invocations in Iconc<sup>Δ</sup>

### 31.6.2 Semantic Analysis

The semantic analysis phase of Iconc<sup>Δ</sup> has been modified in order to identify and complete code transformations initiated in Unicon<sup>Δ</sup>. Each parse tree node representing an invocation is examined during type inferencing in order to identify inter-segment transformational dependencies that remain unsatisfied. Invocation nodes that type inferencing indicates are fields that have the attribute `F_Object` are further examined to determine whether an implicit “self” argument must be added to the argument list of the invocation in order to satisfy an inter-segment transformational dependency. If an unsatisfied dependency exists, the parse tree node corresponding to the invocation is modified in order to achieve semantic closure. Each modified invocation node is marked to prevent superfluous examinations. The parse tree transformations performed during the semantic analysis phase of Iconc<sup>Δ</sup> are simplified by the parse tree transformations performed during the syntax analysis phase of Unicon<sup>Δ</sup>. Many fruitless experiments were performed before determining an effective method of coordinating inter-segment transformations between Unicon<sup>Δ</sup> and Iconc<sup>Δ</sup>. The C code to examine invocations during type inferencing is depicted in Figure 31.6. The C code to insert an implicit self in a method invocation is depicted in Figure 31.7.

The model used by Iconc<sup>Δ</sup> to evaluate subexpressions during type inferencing has been modified. The necessity of this modification was exposed during the analysis of code transformation experiments that did not provide semantic closure for a specific domain of expressive inputs. Expressions of the form

```

static
void
methodinvok_add_implicit_self(n)
    struct node * n;
{
    int i;
    int nargs;
    struct node * t;
    struct node * lhs;

    nargs = Val0(n);
    lhs = Tree0(Tree1(n)); /* lhs of subordinate N_Field */

    if (nargs > 0 && (n->n_field[2].n_ptr->n_col == 123456789 ||
        (n->n_field[2].n_ptr->n_type == lhs->n_type &&
         n->n_field[2].n_ptr->n_field[0].n_ptr ==
         lhs->n_field[0].n_ptr))) {
        /*
         * We have already added the implicit self arg to this
         * method call in an earlier typinfer iteration, or it
         * was supplied in the unicon-generated code; move on.
         */
        return;
    }
    t = dupnode(lhs);
    t->n_col = 123456789; /* mark this node as visited */
    i = node_descendants(n);
    n->n_field[nargs+2].n_ptr = NewNode(i);
    for (i=nargs; i>0; i--)
        n->n_field[i+2].n_ptr = n->n_field[i+1].n_ptr;
    Val0(n) += 1;
    n->n_field[2].n_ptr = t;
}

```

```

every i := 1 to 5 do {
  ((__1 := (__1 :=
  k.nodes_table[i])) &
  (if __1["add_opening"] then __1.add_opening()
  else (__1.__m.add_opening(__1)))) ;
};

```

Figure 31.8: Subexpression Propagation Example

```

procedure main(argv)
  local n, k;

  k := 3;
  n := (n := (2 * k));
  write("n: ", image(n));
end

```

Figure 31.9: Simple Subexpression Propagation Example

$$e_1 := e_2$$

were incorrectly evaluated if subexpression  $e_2$  contained an assignment to the same l-value represented by subexpression  $e_1$ . The sequence of types assumed by an Icon variable during a chain of assignments was in some cases not being propagated beyond the first subexpression in which an assignment was made to said variable. This applicative anomaly was perturbed by generating code in  $\text{Unicon}^\Delta$  that aggressively reused temporary variables. An example of code generated by  $\text{Unicon}^\Delta$  that provoked this behavior is shown in Figure 31.8. In this example, the type held in the temporary `__1` was not propagated to the expression containing the ultimate assignment to `__1`, and the code generated by  $\text{Iconc}^\Delta$  for the entire righthand side of the conjunctive was invalid. A simpler, hand-crafted example depicting a scenario where this behavior was present is shown in Figure 31.9.

Investigation revealed that the applicative order of expression evaluation was being violated during type inferencing in  $\text{Iconc}$ . The type information associated with the innermost assignment to `__1` in Figure 31.8 was being cleared in order to produce the type information pertaining to the ultimate assignment to `__1`. The immediate workaround for this problem was to implement transformations in  $\text{Unicon}^\Delta$  that were lax in their use of temporary variables. The semantic analysis phase of  $\text{Iconc}^\Delta$  was eventually modified to perform an additional check during type inferencing to ensure that type information associated with a variable is not cleared before said information is used to update the type information associated with the same variable.

### 31.6.3 Code Generation

The code generation phase of Iconc<sup>Δ</sup> has been modified to capitalize on the modifications introduced in Section 31.6.1 that permit compile-time differentiation between records representing class instances and records representing records. The primary motivation behind these modifications is to increase the efficiency of method invocations in compiled Unicon programs.

Logic has been added inside Iconc<sup>Δ</sup> to examine field references during code generation. Any detected references to fields within records that represent class instances are passed to additional logic that queries the vtbl (vector table) of the represented class to perform symbol resolution. If a field reference is an invocation and the record containing the field represents a class instance, control is passed to additional logic that generates an invocation of the resolved method. Method invocations are generated using generic Icon descriptors so that the run-time reassignment of methods will not produce erroneous results. Adversarial programs can be constructed that will prevent the current version of Uniconc from correctly determining at compile-time whether an invocation is a procedure or method. In such a case, the current version of Uniconc generates invalid code. Research is currently underway to generate code to differentiate between method and procedure invocations at run-time in the case where compile-time information is insufficient to perform complete disambiguation.

## 31.7 Optimizations In Compiled Targets

This section describes optimizations that Uniconc currently performs when generating compiled targets. Some of these optimizations are specifically tailored for compiled Unicon targets, whereas others are applied when generating either compiled Icon or Unicon targets. Each proposed optimization is presented in a separate section containing appropriate background material, the nature of the optimization, and the preliminary results obtained by applying the optimization.

### 31.7.1 Representation of Class Instances

This section describes a proposed Uniconc optimization that fundamentally modifies the representation of class instances in compiled Unicon targets. This optimization is aggressive and fairly complex. This optimization is primarily time-directed, but also decreases the space required to represent a Unicon class instance in compiled Unicon targets.

A series of transformations is performed on Unicon source code to produce Icon source that is translated by the Icon translator Icont, and subsequently executed by the Icon interpreter Iconx. A sample Unicon program for illustrative purposes appears in an appendix of [Wilder06].

Classes are not native to Icont or Iconx. Instead they are translated into a collection of procedures and records recognized as traditional Icon constructs by Icont and Iconx. Transformations

```

record fifo__state(__s,__m,m_data)
record fifo__methods(get,peek,put,size,initially,buf)
global fifo__oprec, buf__oprec
procedure fifo()
local self,clone
initial {
    if /fifo__oprec then fifoinitialize()
    if /buf__oprec then bufinitialize()
    fifo__oprec.buf := buf__oprec
}
self := fifo__state(&null,fifo__oprec)
self.__s := self
self.__m.initially(self,) | fail
return self
end

procedure fifoinitialize()
    initial fifo__oprec := fifo__methods(fifo_get,fifo_peek,fifo_put,
        fifo_size,fifo_initially)
end

```

Figure 31.10: Unicon Object as Procedural Entity

pertaining to inheritance, method resolution, etc., are performed on the Unicon source to produce semantically equivalent procedural code acceptable to Icon.

The current code generation model produces two record declarations to represent each class. For example, the record `fifo__methods` contains a field for each member method of a `fifo` class. A single instance of a `fifo__methods` record is created at run-time and shared by all `fifo` objects. Each `fifo` instance refers to this methods vector through the `__m` field of its corresponding record `fifo__state`. One `fifo__state` record instance is created for each run-time `fifo` object. The `fifo__state` record contains fields for all member variables in a `fifo` instance, a field for the implicit `self` member specific to object-oriented programming languages, and the aforementioned methods vector `__m`.

A code snippet from [Wilder06] illustrating the internal representation of a Unicon object in the procedural realm of Icon appears in Figure 31.10. The procedure `fifo` represents the constructor of a `fifo` object. The first call to this constructor instantiates a `fifo__methods` record named `fifo__oprec` containing all procedures representing the methods contained in the `fifo` class. The procedure `fifo` creates an instance of the `fifo__state` record, populates the `__m` and `__s` fields with the methods vector and self reference, respectively, and invokes the `initially` procedure corresponding to the

```

struct fentry { /* field table entry */
    struct fentry *blink;      /* link for bucket chain */
    char *name;               /* name of field */
    struct par_rec *rlist;     /* head of list of records */
};

```

Figure 31.11: Field Representation in Iconc

procedure `fifo_initially` to initialize the explicit member variables of this `fifo` instance.

A variable in the Unicon or Icon programming language may assume many types over its lifetime, and variables in these languages need not be declared before their use. This flexibility contributes admirably to the rapid development model for which these languages are renowned, and is simultaneously a source of consternation when attempting to translate down to a high level language with a more rigid type system. Iconc employs a type inferencing system based upon global data flow analysis to determine the types that any variable may take during specific points of program execution. Empirical data suggests that this type inferencer is highly effective. The code generation model of Unicon uses global variables to represent class-wide data shared among Unicon class instances.

Records are used to implement abstract data types in Icon, and Unicon classes are themselves represented as Icon records. Because Unicon is an object-oriented programming language, it provides mechanisms for the encapsulation of data and operations within an object or l-value, and permits the access or mutation of objects through field references associated with the object to be manipulated. The typing system used by the Iconc type inferencer treats records with particular rigor. Each Icon record is considered a distinct type, and each field within each record is itself a distinct type. This treatment of records contributes to the thorough analysis of the flow of data among Icon variables and facilitates the generation of efficient C code to represent Icon expressions.

When a field reference is encountered during the parsing of Icon code, Iconc creates a node in its internal parse tree corresponding to the field reference. Iconc instantiates a `struct fentry` of the form seen in Figure 31.11 for each field encountered. The declaration of a `struct fentry` reveals that Iconc associates a list of `struct par_rec` with each field entry. The `struct par_rec` list represents all records containing a field of a given name. The declaration of `struct par_rec` appears in Figure 31.12.

All `struct fentry` instances are hashed using the name of the field as the hashing key. The `struct par_rec` declaration contains the field offset for the field of a given name within a particular parent record. When a field reference is encountered in the parse tree during type inferencing, Iconc infers the types that the record may assume at the location of the field reference during program execution. Iconc then uses the name of the field to which the code refers to determine the parent records associated with the field and the offsets of the field within said parent records. This information is used in the event that a lefthand side of a field reference may assume multiple

```

struct par_rec { /* list of parent records for a field name */
    struct reentry *rec;      /* parent record */
    int offset;               /* field's offset within this record */
    int mark;                 /* used during code generation */
    struct par_rec *next;
};

```

Figure 31.12: Parent Record Representation in Iconc

```

{
/* Ikup undo__UndoableEdit */
struct b_record *r_rp = (struct b_record *)
    BlkLoc(r_f.t.d[0] /* self */);
r_f.t.d[2].dword = D_Var +
    ((word *)&r_rp->fields[8] - (word *)r_rp);
VarLoc(r_f.t.d[2]) = (dptr)r_rp;
}

```

Figure 31.13: Iconc Code Generated for Unambiguous Field Reference

types at a given point in program execution. The information regarding the types that the field may assume during program execution is stored in a specific area of the parse tree node representing the field reference.

If the type of a record can be determined unambiguously at compile-time, Iconc generates code that directly accesses a referenced field in the record. The code that Iconc generates in this case is of the form seen in Figure 31.13. In this case, the Iconc type inferencer has determined that the lefthand side of the field reference at this code point can only take one type during program execution, and Iconc has determined the offset of the field to be accessed by examining the struct par\_rec corresponding to the type of the record.

Often the Iconc type inferencer determines that the lefthand side of a field reference at a given code point may assume more than one record type during program execution. In this case, Iconc examines all records associated with the types that the lefthand side may assume and, if only a single record contains a field of the name specified at that code point or if the field to be referenced is at the same offset within all records containing the field, Iconc is still able to generate code that is of the form seen in Figure 31.13.

In many cases, however, more than one record contains a field of the name specified in the field reference, and the offsets for the named field within one or more of these records is not the same. In this case, Iconc generates a C switch statement to perform a run-time check to determine the type of the record being accessed and the offset of the field within that record. The code generated by Iconc in this instance is of the form shown in Figure 31.14.

```

{
/* Ikup MaxChars */
struct b_record *r_rp = (struct b_record *)
    BlkLoc(glbl_argp[0] /* self */);
dptr r_dp; int fld_idx;
switch (r_rp->recdesc->proc.recnum) {
    case 127:
        r_dp = &r_rp->fields[4];
        break;
    case 285:
        r_dp = &r_rp->fields[1];
        break;
    default:
        if ((fld_idx = fldlookup(r_rp, "MaxChars")) < 0)
            err_msg(207, &glbl_argp[0] /* self */);
        else
            r_dp = &r_rp->fields[fld_idx];
    }
r_f.t.d[11].dword = D_Var + ((word *)r_dp - (word *)r_rp);
VarLoc(r_f.t.d[11]) = (dptr)r_rp;
}

```

Figure 31.14: Iconc Code Generated for Ambiguous Field Reference

In this case Iconc generates code to examine the record number of the lefthand side of the field reference and assigns the correct field offset based upon the number (type) of the record being accessed. This information is gathered from the struct fentry and struct par\_rec lists at compile-time.

### 31.7.1.1 The Proposed Optimization

This optimization originated as a time-directed optimization during the experimentation with and analysis of C code generated for Unicon source. Since Unicon is object-oriented, an obvious path to faster generated code seemed to be through the tailoring of field references. The reader will recall that a method reference in Unicon source is actually presented as a pair of field references to Iconc. The first reference is to obtain the `__m` field (methods vector) of the object, and the second is to access the desired field containing the desired method. The primary goal at the outset of this optimization work was to eliminate this extra field reference in compiled Unicon targets.

The first step toward eliminating the extra field reference for method invocations in compiled Unicon targets was to modify the Unicon code generation model. Unicon<sup>Δ</sup> was modified to eliminate all references to `__m` and `__s` in generated code targeted for Iconc<sup>Δ</sup>. The translation of a Unicon class into Icon records was modified to facilitate the removal of `__m` and `__s`.

Comparing the generated code produced by this optimization with previous generated code reveals several points of interest worthy of discussion. The record `fifo__methods` declaration and its instance `global fifo__oprec` are the same in both of these appendices. This is due to the fact that the proposed optimization retains the previous behavior of using a single, shared methods vector among all instances of a Unicon class. The previous representation of the `fifo` class from an in appendix in [Wilder06] as shown below

```
record fifo__state(__s,__m,m_data)
record fifo__methods(get,peek,put,size,initially,buf)
```

now appears as

```
record fifo__mdw_inst_mdw(m_data,get,peek,put,size,initially,buf)
record fifo__methods(get,peek,put,size,initially,buf)
```

in the code generated by Unicon<sup>Δ</sup> as modified for this proposed optimization. The reader will immediately note that the `fifo__mdw_inst_mdw` declaration, the counterpart to the `fifo__state` declaration under the previous translation model, has more fields than the previous `fifo__state`, and that the record `fifo__mdw_inst_mdw` declaration contains fields that are redundant with those contained in the record `fifo__methods` declaration. This is intended.

The field redundancy between the `fifo__methods` and `fifo__mdw_inst_mdw` records under the proposed optimization is a bit of trickery directed at the Iconc<sup>Δ</sup> parser. This field redundancy leads Iconc<sup>Δ</sup> to permit the notation

`r.add()` invocation  $P$

where

`r.__m.add()` invocation  $O$

was previously required. When Iconc<sup>Δ</sup> parses invocation  $P$ , it determines that invocation  $P$  is syntactically correct due to this intentional field redundancy. After type inferencing is complete, the redundant fields in the struct `rentry` of the struct `par_rec` that Iconc<sup>Δ</sup> builds to represent the struct `fifo__mdw_inst_mdw` are removed. This removal makes these fields and their offsets inaccessible to the Iconc<sup>Δ</sup> code generator. The removal of redundant fields from Iconc records representing Unicon class instances is accomplished by the source code depicted in Figure 31.15.

All field references are examined during the code generation phase of Iconc<sup>Δ</sup>. If a given field reference is an invocation and the type of the field is of one or more Unicon class record instances, control is passed to additional logic added inside Iconc<sup>Δ</sup> to resolve the particular vector table to which the reference is directed.

### 31.7.1.2 Results

The reader will recall that the code to add a datum to a `fifo` as it appears in the sample program in an appendix of [Wilder06] is `f.put("1st")` as shown in the procedure `fifo_test`. A snippet of code generated by Iconc to perform the above invocation using the methodology existing prior to this proposed optimization appears in Figure 31.16. Under this proposed optimization, Iconc<sup>Δ</sup> generates code to perform this same invocation as shown in Figure 31.17.

Consideration of Figure 31.16 and Figure 31.17 reveals that an extra field reference is indeed saved using the proposed optimization. The savings in time realized by this optimization will be proportional to the number of method invocations executed by a compiled Unicon program. Another effect of the proposed optimization is the decrease of run-time space required to represent a Unicon object in code generated by Iconc<sup>Δ</sup>. The space required to represent two descriptors in compiled Unicon targets is eliminated for each run-time instance of a Unicon class under the proposed optimization because the fields `__m` and `__s` are no longer used. Measurements verifying the space savings introduced by this optimization are described in Section 31.8.4. This side effect will likely prove beneficial in large-scale, object-oriented applications where Unicon is typically deployed.

## 31.7.2 Invocations

This section describes a proposed Uniconc optimization that modifies numeric parameters passed to invocations in compiled Unicon and Icon targets. This optimization is primarily time-directed.

```

static
void
adjust_class_recs(recs)
    struct reentry * recs;
{
    int nflds;
    char * p, * q;
    struct fldname * f;
    struct reentry * rinst;
    struct reentry * rmeth;

    for (rinst=recs; rinst; rinst=rinst->next) {
        if ((p = strstr(rinst->name, "__mdw_inst_mdw")) == NULL)
            continue;
        for (rmeth=rinst->next; rmeth; rmeth=rmeth->next) {
            if ((q = strstr(rmeth->name, "__methods")) == NULL)
                continue;
            if (p - rinst->name != q - rmeth->name)
                continue;
            if (strncmp(rinst->name, rmeth->name, p - rinst->name))
                continue;
            nflds = rinst->nfields - rmeth->nfields;
            while (rinst->nfields > nflds) {
                f = rinst->fields;
                rinst->fields = rinst->fields->next;
                free(f);
                rinst->nfields--;
            }
            break;
        }
    }
}

```

```

Figure 31.17: Sample Method Invocation in Iconc<sup>Δ</sup>

### 31.7.2.1 Background

The RTL<sup>Δ</sup> contains a generalized invocation function called `invoke`. Code generated by Iconc and Iconc<sup>Δ</sup> calls `invoke` in order to accomplish the invocation of a procedure or function represented by a procedure descriptor or a string descriptor. The signature of `invoke` appears in the RTL<sup>Δ</sup> as shown in Figure 31.18. The `dptr` type shown in Figure 31.18 is a pointer to a descriptor. Descriptors are used in the RTL<sup>Δ</sup> and the Icon VM to generically describe the type and value of Icon and Unicon run-time entities. A typical invocation of `invoke` before the proposed optimization is shown in Figure 31.19.

### 31.7.2.2 The Proposed Optimization

This optimization adds logic to Iconc<sup>Δ</sup> in order to determine at compile-time the value held by the integer descriptor that is declared as the formal argument `nargs` for each invocation of the `invoke` function. This optimization is enabled whenever using Uniconc to produce a compiled target. The logic added to Iconc<sup>Δ</sup> by this optimization creates a temporary compile-time descriptor which is marked to be accessed as an integer literal containing the value of the integer descriptor that would normally be used to accomplish the invocation. This temporary descriptor is used by the Iconc<sup>Δ</sup> code generator to populate the codestream with the integer literal itself rather than the sequence of field references that are normally used to access the integer literal within the given descriptor. Figure 31.20 depicts the result of this proposed optimization. The `invoke` function being used to accomplish the invocation of an Icon procedure in a compiled target shown at the end of Figure 31.20 reveals that the logic added to Iconc<sup>Δ</sup> by this proposed optimization indeed inserts an

```

int invoke(nargs, args, rslt, succ_cont)
    int nargs;
    dptr args;
    dptr rslt;
    continuation succ_cont;

```

```

r_f.t.d[6].dword = D_Integer;
r_f.t.d[6].vword.integr = 3;
r_f.t.d[3].dword = D_Var;
r_f.t.d[3].vword.descptr = &r_f.t.d[0] /* f */;
r_f.t.d[4].vword.sptr = "1st";
r_f.t.d[4].dword = 3;
invoke(r_f.t.d[6].vword.integr, &r_f.t.d[2], &r_f.t.d[5],
    sig_28);
L29: ; /* bound */

```

Figure 31.19: Sample Invocation in Uniconc Before Optimization

integer literal in the codestream where previously there were a sequence of field references. The logic added to Iconc<sup>Δ</sup> that accomplishes this substitution is shown in Figure 31.21.

### 31.7.2.3 Results

Consideration of Figure 31.19 and Figure 31.20 indicates that eleven field references, three array subscript operations, and two assignment operations are eliminated at run-time for each invocation of `invoke` acted upon by this proposed optimization. This proposed optimization only acts upon those invocations that are not already correctly inlined by Iconc, so the aforementioned benefit is realized if and only if the previously existing Iconc code failed to reduce the descriptor to an integer literal.

```

r_f.t.d[3].dword = D_Var;
r_f.t.d[3].vword.descptr = &r_f.t.d[0] /* f */;
r_f.t.d[4].vword.sptr = "1st";
r_f.t.d[4].dword = 3;
invoke(3, &r_f.t.d[2], &r_f.t.d[5], sig_28);
L29: ; /* bound */

Figure 31.21: Inlining Integer Arguments in Iconc<sup>Δ</sup>

### 31.7.3 Dereferences

This section describes a proposed Uniconc optimization that generates in-line C code in certain cases where a call to the `deref` RTL<sup>Δ</sup> function would normally be generated in compiled Unicon and Icon targets. This optimization is primarily time-directed.

#### 31.7.3.1 Background

Variables in Icon and Unicon may assume many types during the lifetime of a program. The implementors of the Icon interpreter use the notion of a descriptor to generically describe the type and value of a given Icon variable. This method of description is also used in the Icon run-time library, and was subsequently adopted by Iconc. The declaration of a descriptor is shown in Section 4.4.1. Performance analysis of compiled targets using profiling tools indicates that the typical Icon or Unicon program spends an appreciable amount of time dereferencing descriptors in the RTL<sup>Δ</sup> `deref` function.

#### 31.7.3.2 The Proposed Optimization

When the types of the operands to the `deref` operation can be reliably determined at compile-time, there are situations where the functionality provided by the `deref` function can be generated directly in the codestream without entering the RTL<sup>Δ</sup>. In the event that the entity being dereferenced is not a variable, or is a “normal” variable, the code contained in the `deref` function is simple and should provide an opportunity for inlining.

Iconc has been modified to examine the operands of the `deref` operation and to generate the inline equivalent of a `deref` call where appropriate. This optimization is enabled by the `-wb` Uniconc command-line option. This optimization is intended to act only in the case where the dereferenced entity is a “simple” variable, or is not a variable at all.

#### 31.7.3.3 Results

A snippet of code generated by Iconc<sup>Δ</sup> without the proposed optimization is shown in Figure 31.22. In this snippet, the result of `O114_subsc` is used as both the source and destination of a dereferencing operation via the RTL<sup>Δ</sup> `deref` function.

A snippet of code generated by Iconc<sup>Δ</sup> for the same source with the proposed optimization enabled is shown in Figure 31.23. The call to `deref` in Figure 31.22 has been replaced with the inlined equivalent of a `deref` call in Figure 31.23. It should be noted that `VarLoc` and `Offset` are macros in the generated code, so no function call is being made by the inlined substitute for the call to the `deref` function in the RTL<sup>Δ</sup>.

It is likely that the methodology employed by this particular optimization to circumvent a call to an RTL<sup>Δ</sup> operation can be applied to other RTL<sup>Δ</sup> operations in a similar fashion. Applying this

```
deref(&r_f.t.d[5], &r_f.t.d[5]);
```

Figure 31.22: Code Generated Before deref Optimization

```
r_f.t.d[5] = *(dptr)((word *)VarLoc(r_f.t.d[5]) +
    Offset(r_f.t.d[5]));
```

Figure 31.23: Code Generated After deref Optimization

methodology to other RTL<sup>Δ</sup> functions is a potential subject of future experimentation.

## 31.8 Metrics

Uniconc can produce compiled or interpreted Icon and Unicon targets. The purpose of this chapter is to quantify the speedup provided by Uniconc to compiled versus interpreted Unicon code. This speedup is compared to the speedup provided by Uniconc to compiled versus interpreted Icon code. Iconc<sup>Δ</sup> was used for the tests instead of Iconc, initially for the sake of convenience in testing. Subsequent attempts to run the Icon test cases with Iconc from the Icon 9.4.3 distribution failed due to incompatibilities between Iconc and the Icon 9.4.3 run-time system. These incompatibilities likely exist because Iconc is no longer actively supported. The results from Iconc<sup>Δ</sup> for Icon programs depicted in this chapter should be comparable to results obtained from Iconc for these same Icon programs, although the targets generated by Iconc<sup>Δ</sup> will likely be a few percent faster due to the benefits of the dereference inlining optimization described in Section 31.7.3.

### 31.8.1 Overview

A representative set of programs were chosen to catalogue the important functional features of Icon and Unicon while providing a comparative analysis of these features. The set of programs contained herein is by no means exhaustive. The execution speed of some programs are measured with the linux `time(1)` utility, and others are measured using the Icon `&time` keyword. The latter method of measuring execution speed was borrowed from [Walker91]. All measurements were taken on an AMD64 dual-core dual-processor machine running linux (Fedora Core 3). Each processor has a clock speed of 1790.9 MHz and contains 1MB cache.

### 31.8.2 Invocations

Invocations are a cornerstone of any programming language. Difficulties arise when attempting to compare invocations in procedural languages to invocations in object-oriented languages due to the

fact that invocations in object-oriented languages are fundamentally different than invocations in procedural languages.

Figure 31.24 is an Icon program used to measure the speed of invocations in compiled and interpreted Icon targets. Figure 31.25 contains a Unicon program used to measure the speed of invocations in compiled and interpreted Unicon targets. All targets, compiled and interpreted, were generated by the same version of Uniconc. Each target was invoked with a single command-line argument in order to accomplish 10,000,000 invocations. The measurements depicted are the average of three runs of each program. The results are shown below.

Target	average time (ms)		
compiled Icon	703		
interpreted Icon	8,560		
		Icon speedup	<b>1,217%</b>
compiled Unicon	1,190		
interpreted Unicon	10,150		
		Unicon speedup	<b>853%</b>

Figure 31.26 is an Icon program using the Takeuchi function to measure the speed of recursive invocations in compiled and interpreted Icon targets. Figure 31.27 contains a Unicon program using the Takeuchi function to measure the speed of recursive invocations in compiled and interpreted Unicon targets. All targets, compiled and interpreted, were generated by the same version of Uniconc. Each target was invoked with a single command-line argument of the form `tak 27 18 9`. The measurements depicted are the average of three runs of each program taken with the `linux time(1)` utility. The results are shown below.

Target	average time (ms)		
compiled Icon	500		
interpreted Icon	11,400		
		Icon speedup	<b>2,280%</b>
compiled Unicon	2,070		
interpreted Unicon	13,600		
		Unicon speedup	<b>657%</b>

It is apparent that the speedup afforded compiled Unicon invocations by Uniconc is not on par with the speedup afforded compiled Icon invocations by Uniconc. The results are not discouraging, but certainly indicate that further research in this area is necessary.

### 31.8.3 Field References

Field references are a mainstay of object-oriented programs. The speed at which a field reference is accomplished is of paramount concern when evaluating the utility of an object-oriented language.

Figure 31.28 is an Icon program used to measure the speed of field references in compiled and interpreted Icon targets. Figure 31.29 contains a Unicon program used to measure the speed of field references in compiled and interpreted Unicon targets. All targets, compiled and interpreted, were generated by the same version of Uniconc. Each target was invoked with a single command-line argument in order to accomplish 10,000,000 field references. The measurements depicted are the average of three runs of each program. The results are shown below.

Target	average time (ms)		
compiled Icon	760		
interpreted Icon	8,500		
		Icon speedup	<b>1118%</b>
compiled Unicon	760		
interpreted Unicon	8,610		
		Unicon speedup	<b>1133%</b>

The results indicate that the speedup afforded compiled Unicon field references by Uniconc is similar to the speedup afforded compiled Icon field references by Uniconc.

### 31.8.4 Space Savings In Compiled Targets

Section 31.7.1 describes an optimization for compiled targets that reduces the size of class instances in compiled Unicon targets. This section verifies the space savings offered by the aforementioned optimization.

A sample Unicon program that measures the size of the string and block regions used by the program appears in Figure 31.30. The memlog procedure used in this program is the work of Gregg M. Townsend of the University of Arizona. This program merely instantiates a specified number of instances of the `fivemembers` class, and invokes `memlog` to emit the usage of the string and block regions by the program as it progresses. The `STRSIZE` and `BLKSIZE` environment variables were set to a very large value while running the program to ensure that no collections occurred. The invocation of `memlog` could and probably should be moved to the very end of the main procedure, but it was left inside the instantiation loop to permit measurements using this program when collections are permitted to occur.

When this program was run with command-line arguments necessary to create 500 instances of the `fivemembers` class, the following results were observed:

Target	usage of regions (bytes)
compiled Unicon	str:0/36277125(0) blk:56160/36277125(0)
interpreted Unicon	str:3/36277125(0) blk:72160/36277125(0)
	block region savings <b>16,000</b> bytes

This result is consistent with the expectation that the space of two Unicon descriptors is saved per class instance under the optimization proposed in Section 31.7.1. The program was also run with command-line arguments necessary to create 1,000 instances of the `fivemembers` class, with the following results:

Target	usage of regions (bytes)
compiled Unicon	str:0/36277125(0) blk:112160/36277125(0)
interpreted Unicon	str:4/36277125(0) blk:144160/36277125(0)
	block region savings <b>32,000</b> bytes

This result is also consistent with the expectation that the space of two Unicon descriptors is saved per class instance under the optimization proposed in Section 31.7.1.

These measurements only verified that the space of two descriptors per class instance is saved by the optimization proposed in Section 31.7.1. The impact of this savings realized will vary depending upon the nature of the application being compiled by Uniconc. It is vacuously true that an increasing number of object instances will result in a higher savings of space.

### 31.8.5 General Programs

The quicksort algorithm was selected as a benchmark primarily because of its ubiquity. It is also recursive, and sorts in place so the number of allocations is likely reduced. Figure 31.31 shows the Icon implementation of quicksort used for this measurement, and Figure 31.32 shows the Unicon implementation of quicksort used. All targets, compiled and interpreted, were generated by the same version of Uniconc. Each target was invoked with a single command-line argument in order to accomplish the sorting of 200,000 pseudorandom values. The measurements depicted are the average of three runs of each program taken with the `linux time(1)` utility. The results are shown below.

Target	average time (ms)		
compiled Icon	1,090		
interpreted Icon	4,790		
		Icon speedup	<b>440%</b>
compiled Unicon	1,260		
interpreted Unicon	6,090		
		Unicon speedup	<b>483%</b>

The seed used by the pseudorandom number generation facility in Icon and Unicon is the same for each program, and the values being sorted by the programs are therefore the same. The results indicate that the speedup afforded compiled Unicon by Uniconc for such a sorting program is comparable to the speedup afforded compiled Icon by Uniconc.

A pair of appendices in [Wilder06] contain the listing for an I/O-intensive Unicon program that creates an arbitrary number of Unix resource files containing an arbitrary number of topics in each file, followed by the listing for the Icon counterpart to the aforementioned Unicon program. All targets, compiled and interpreted, were generated by the same version of Uniconc. Each target was invoked with command-line arguments to accomplish the creation of 50 resource files, with each file containing 500 topics. The filesystem was cleared of resource files created for a given program run after each run was measured. A new class instance (in Unicon) or record instance (in Icon) is created for each resource file. The measurements depicted are the average of three runs of each program taken with the linux time(1) utility. The results are shown below.

Target	average time (ms)		
compiled Icon	1,030		
interpreted Icon	4,960		
		Icon speedup	<b>481%</b>
compiled Unicon	1,080		
interpreted Unicon	5,060		
		Unicon speedup	<b>468%</b>

This particular set of measurements is not very interesting since the results are bounded by I/O. The results do indicate, however, that Uniconc performs comparably for compiled Icon and Unicon targets that are bound by I/O.

The measurements contained in this section were taken with all optimizations enabled in Iconc<sup>Δ</sup>. It should be noted that Iconc<sup>Δ</sup> has been produced from modifications to Iconc, so the results obtained on Icon programs with an unmodified Iconc will likely be different than those observed herein. The full effect of the class instance representation optimization described in Section 31.7.1 was not measured in this section because no appropriate basis point for such a measure-

ment exists. In a general sense, the measurements in this section indicate that the speedup provided by Uniconc for compiled Unicon targets is about the same as the speedup provided by Uniconc for compiled Icon targets.

```

procedure p()
    return;
end

procedure main(argv)
    local n, clk;

    n := integer(argv[1]);
    clk := &time;
    while (n > 0) do {
        p();
        n -= 1;
    }
    clk := &time - clk;
    write("time: ", clk);
end

```

Figure 31.24: Icon Program Measuring Invocations

## 31.9 Future Work

Uniconc is an experiment in progress. Limitations exist in the version of Uniconc described in this chapter. There are also potential improvements that can be made to Uniconc in addition to addressing its limitations. This chapter discusses the limitations of the current version of Uniconc, describes some of the approaches that are being considered to eliminate or alleviate these limitations, and describes potential improvements in generated targets.

### 31.9.1 Limitations

The version of Uniconc described in this chapter contains limitations pertaining to scalability, disambiguation, and introspection. Each of these limitations are characterized in this section, and the current approaches being considered to address each of these limitations are described.

```

class o()
  method p()
    return;
  end
end

procedure main(argv)
  local n, x, clk;

  x := o();
  n := integer(argv[1]);
  clk := &time;
  while (n > 0) do {
    x.p();
    n -= 1;
  }
  clk := &time - clk;
  write("time: ", clk);
end

```

Figure 31.25: Unicon Program Measuring Invocations

### 31.9.1.1 Scalability

Uniconc currently has a scalability issue that prevents the compilation of large, class-intensive programs with computational resources available to the typical user. Sources of this scalability issue are:

- The parse tree for an entire program is maintained in memory by Iconc<sup>Δ</sup> for the duration of compilation. This includes nodes corresponding to unreachable control paths in source programs.
- The representation of type vectors used by Iconc<sup>Δ</sup> grows very large when many distinct types are used within a program. This is particularly evident in Unicon programs where many classes (records) are used.
- The representation of type vectors used by Iconc<sup>Δ</sup> can become pathologically sparse when many distinct types are used within a program. This is particularly evident in Unicon programs containing many classes.

Experiments to improve the scalability of Uniconc during the course of this project have thus far proven unsuccessful. The preliminary underpinnings of further Uniconc scalability experiments are currently being planned. Three avenues of approach to this problem are currently being entertained. These approaches are:

Approaches i and ii above will unfortunately only provide a transient alleviation of the symptoms

```

procedure tak(x, y, z)
  if not (y < x) then
    return z
  else
    return tak(tak(x-1, y, z), tak(y-1, z, x), tak(z-1, x, y));
end

procedure main(argv)
  tak(integer(argv[1]), integer(argv[2]), integer(argv[3]));
end

```

Figure 31.26: Icon Takeuchi Function

that characterize the Uniconc scalability problem. It is likely that one or more of these approaches will be attempted, however, in order to permit the compilation of larger Unicon programs with typically available computational resources in the near term.

Approach iii is currently the only path that may provide a solution to the Uniconc scalability problem. It is unknown, however, whether this approach is navigable. Multiple gedankenexperiments have to this date been conducted using approach iii, and the feasibility of the approach is still in doubt. It is possible that separately compiled modules in Uniconc can be modelled after the approach currently taken with builtin functions in the RTL<sup>Δ</sup>. This approach might also use the type coercion syntax currently found in the RTL<sup>Δ</sup> implementation language to improve the quality of the code generated for Unicon modules. It would be far more desirable, however, to devise a technique that supports the separate compilation of Unicon modules without marring the syntactic or semantic elegance of Unicon. The Uniconc scalability issue will be a primary focus of continuing research.

### 31.9.1.2 Lack of Introspection

The Unicon GUI class library uses facilities that examine the members of Unicon class instances at run-time. This introspective capability is very important for large-scale, dynamic, object-oriented programs. Uniconc is not currently able to correctly compile the Unicon GUI class library because the introspective capabilities used in this library are highly dependent upon the internal representation of Unicon classes. The representation of Unicon class instances has been fundamentally modified by Uniconc as described in Section 31.7.1 in order to produce savings in space and time. Unfortunately, the modifications directly conflict with the current introspective capabilities of the Unicon GUI class library. If the optimization proposed in Section 31.7.1 is adopted, the introspective capabilities in the Unicon GUI class library will need to be modified to accommodate this change. It is likely that a new function called `methodnames` could be added to the Uniconc RTL<sup>Δ</sup> in order to satisfy the inherently dynamic requirements of introspection while insulating the Unicon

```

class tak()
  method comp(x, y, z)
    if not (y < x) then
      return z
    else
      return comp(comp(x-1, y, z), comp(y-1, z, x),
                  comp(z-1, x, y));
    end
  initially(x, y, z)
    comp(x, y, z);
  return;
end

procedure main(argv)
  local t;
  t := tak(integer(argv[1]), integer(argv[2]), integer(argv[3]));
end

```

Figure 31.27: Unicon Takeuchi Function

GUI class library from a priori knowledge regarding the peculiarities of the internal representation of Unicon classes. In the event that the introspective behavior of compiled Unicon applications can be unambiguously determined by Uniconc at compile-time, the functionality provided by a run-time call to `methodnames` can be inlined by Iconc<sup>Δ</sup>.

### 31.9.1.3 Disambiguation

The Iconc<sup>Δ</sup> code generator currently does not correctly differentiate between methods and procedures in the case where the member variable of a class instance is reassigned with a procedure. Figure 31.33 depicts a situation where the Iconc<sup>Δ</sup> code generator currently fails. In particular, the code generated for the invocation of the member variable `x` in class `f00` shown in Figure 31.33 will be invalid. This is because the lefthand side of the generated `self.x()` invocation is a class instance, so an implicit self argument will be added to the invocation by the Iconc<sup>Δ</sup> code generator. A potential avenue of approaching the solution to this error has been devised, but the experimentation required to achieve a solution has not yet been performed.

The disambiguation methodology currently employed by Iconc<sup>Δ</sup> contains a flaw that permits the crafting of adversarial Unicon programs that will defeat said disambiguation. A method for identifying these adversarial situations in Unicon programs has been devised, and a scheme for generating code to defer disambiguation until run-time in these instances will likely be implemented to plug this hole in the near term. Research is currently being undertaken to refine the disam-

```

record rec(x)

procedure main(argv)
    local n, r, clk;

    n := integer(argv[1]);
    r := rec(11);
    clk := &time;
    while (n > 0) do {
        v := r.x;
        n -= 1;
    }
    clk := &time - clk;
    write("time: ", clk);
end

```

Figure 31.28: Icon Program Measuring Field References

biguation methodology used by Iconc<sup>Δ</sup> in order to decrease the likelihood of requiring run-time disambiguation in adversarial Unicon programs.

### 31.9.2 Potential Improvements

Uniconc provides a space savings of two descriptors per class instance in compiled versus VM-hosted Unicon targets. Greater savings in space for compiled Unicon programs may be possible by extending the class instance representation optimization described in Section 31.7.1.

A speedup of compiled Unicon targets may be possible by reordering the fields of a class instance presented to Iconc<sup>Δ</sup> in such a manner that methods vectors inherited from the superclasses of a given class are ultimately placed in the lower-ordered fields of the struct reentry created by Iconc<sup>Δ</sup>. This would increase the likelihood that superclass methods vectors shared by class instances would occupy the same slot indices, thereby permitting the generation of faster code for run-time accesses to said fields.

The speedup provided by Uniconc for compiled targets can potentially be improved by extending the Iconc<sup>Δ</sup> code generator to eliminate the use of descriptors in generated code where possible. The quality of information provided by the Iconc<sup>Δ</sup> type inferencer is a primary enabler of this possibility.

Iconc was originally designed to manipulate user programs directly. Uniconc uses Iconc<sup>Δ</sup> to manipulate code generated by Unicon<sup>Δ</sup>; a very different role. It is likely that the set of potential expressive inputs to Iconc<sup>Δ</sup> can be reduced by Unicon<sup>Δ</sup>, thereby providing a smaller mapping domain for code transformations performed in Iconc<sup>Δ</sup>. A smaller mapping domain in Iconc<sup>Δ</sup> may

```

class o(m_x)
  method run(n)
    local v, clk;
    clk := &time;
    while (n > 0) do {
      v := self.m_x;
      n -= 1;
    }
    clk := &time - clk;
    write("time: ", clk);
  end
initially(n)
  run(n);
end

procedure main(argv)
  local n, r;

  n := integer(argv[1]);
  r := o(n);
end

```

Figure 31.29: Unicon Program Measuring Field References

illuminate further opportunities for optimizing the C source generated by Iconc<sup>Δ</sup>.

## 31.10 Conclusion

Uniconc is a useful tool for conducting code transformation experiments. The visibility into code transformation experiments imparted by the topology of Uniconc should prove beneficial for exploring the optimizational peculiarities of goal-directed and goal-directed, object-oriented programming languages.

Preliminary results suggest that compiled targets generated by Uniconc are generally at least 400% faster than VM-hosted targets generated by Uniconc. In some cases the improvement in speed appears much larger. This speedup is the direct result of attempting to lower user programs toward the target machine. The speedups observed were not obtained at the expense of program readability or flexibility; the “orthogonality to the mainstream” [Griswold78] mantra has thus far been preserved.

The speedup provided by Uniconc for compiled Unicon targets is about the same as the speedup

provided by Uniconc for compiled Icon targets. Several optimizations were implemented, primarily to reduce the time and space overhead associated with object-oriented code. Further research is necessary in the area of speedup improvement for invocations in compiled Unicon targets.

```

## Chapter 32

# Concurrency and Thread-Safety

A *thread* is a fundamental building block of an executing program, consisting of a set of registers (including a program counter indicating what instruction it is executing) and a stack with which to evaluate intermediate results, place parameters and perform function calls, etc. If you have a running program, you have one thread; if you have multiple threads, you might have one running at a time and the threads taking turns, or you might have more than one running simultaneously, a condition known as concurrent execution.

Icon's co-expression type is a thread-type that does not allow concurrent execution. In fact, the current implementation of Icon uses posix threads with simple rules to ensure that only one of them at a time can ever execute.

Since the turn of the 21st century, however, concurrency has become essential to utilizing modern computer processors. Once CPU manufacturers hit physical limits and could no longer double the clock speed every 18 months, they have turned a large part of their attention to the addition of more and more execution cores at a given clock speed. Because multiple cores are now ubiquitous, and concurrent programming is notoriously difficult, the pressure on very-high level languages to support concurrency is high, but adding concurrency to a very high-level language is more difficult than it might seem. Most popular mainstream scripting languages offer pseudo-concurrency, but true concurrency is often limited by a "global interpreter lock", or GIL, that prevents simultaneous access by multiple threads to the same virtual machine.

In order to provide true concurrency, Unicon extends Icon's posix threads co-expression implementation, and provides a thread-safe runtime system. Some of this was accomplished by switching out unsafe C library functions for their thread-safe counterparts, but a far more substantial part of it was accomplished by making threads as independent of each other as possible, giving each thread its own copy of various interpreter state variables that formerly were globals. This is one of the few semantic differences between Icon and Unicon.

## 32.1 Thread State

Unicon's threads implementation was influenced heavily by the earlier development of dynamic loading and the ability to execute multiple programs as co-expressions within the same virtual machine. That earlier implementation produced a notion of a "current program state" embodied by a struct progstate. Concurrent threads share parts of what was the progstate, while giving each thread its own copy of as many parts as possible in order to minimize threads' interference with each other. Those parts of the global state that are replicated on a per-thread basis form struct threadstate in src/h/rstructs.h.

From a language design standpoint, adding concurrency to Unicon consisted of:

1. adding a way to tell co-expressions to execute concurrently instead of waiting to be activated.
2. extending the activation operator @ and adding new operators to provide a simple mechanism for thread synchronization and communication. These were achieved by introducing a new reserved word thread and extending the @ operator to maintain producer-consumer queues for asynchronous operation in addition to operators for new forms of synchronization and communication as discussed later in this section. The thread syntax can be used in the following manner:

thread expr

The language was also extended with several new built-in functions for high-level access to mutual exclusion primitives and condition variables, in addition to extending a few existing functions to support new semantics. For example, the built-in function wait() was extended to allow a thread argument to support the semantics of join in thread programming. Many of the extensions have to do with synchronization. Some problems require using advanced synchronization mechanisms and rely on the language support to achieve full control over the execution of threads and protect shared data. This section covers the synchronization techniques introduced into the Unicon language. It also covers thread communication and the new communication operators.

## 32.2 Synchronization

### 32.2.1 Critical Regions and Mutexes

A mutex is a synchronization object used to protect shared data and serialize threads in critical regions. For example when two threads compete to increment a variable, the end result might not be what the programmer intended. In such cases a mutex should be used to protect access to the variable. Any operation or data where more than one thread can execute non-deterministically, leading to data corruption or incorrect results is called thread unsafe. Thread unsafe code or data

structures have to be handled correctly via synchronization mechanisms to achieve correct behavior with correct results. A mutex object can be created using the `mutex()` function. The returned mutex object can then be locked/unlocked via the functions `lock()` and `unlock()` to serialize execution in a critical region. Unicon provides a special syntax for critical regions which is equivalent to a `lock()/unlock()` pair, that aims mainly to guarantee that a mutex is released at the end of a critical region, beside enhancing the readability of the program. Here is the syntax:

```
critical mtx: expr
```

This is equivalent to:

```
lock(mtx)
expr
unlock(mtx)
```

The initial clause is thread-safe. It can be thought of as a built-in critical region that is run only once. No thread is allowed to enter the procedure if there is a thread currently still executing in the initial block. This can be useful specifically in a concurrent environment to do critical initialization such as creating a new mutex object instead of declaring a mutex variable to be global and initializing it somewhere else or passing it from one function to another where it will be actually used. A concurrent version of `seq()` would look like this:

```
procedure seq()
  local n
  static i, region
  initial {i:=0; region:=mutex()}
  critical region: n := i := i+1
  return n
end
```

Mutexes do not exist solely as independent objects, they are also used as attributes of other objects, namely attributes of the mutable data types. Any data structure in Unicon that can be used in a thread unsafe manner is better protected by a mutex. Instead of declaring a separate mutex, locking and unlocking it, the structure can just be marked as needs a mutex/protection and the language does an implicit locking/unlocking, protecting the operations that might affect the integrity of the data structure. For example, if several threads are pushing and popping elements into and out of a list, this creates thread-unsafe operations on the list that require protection. Using a thread-safe list results in less lines of code compared with doing explicit locking, and also produces a more efficient program doing less locking and unlocking at the language level, or even not doing at all. For example, a list can be protected by passing it to the function `mutex()` as follows:

`mutex(L)`

From this point on, any puts to the list or gets from `L` are protected by an implicit mutex locking mechanism. This helps make concurrent programming almost as easy as writing a sequential program. The only needed step is to notify the language at the beginning that the data structure is shared, by passing it to the `mutex()` function. Having to explicitly mark structures as shared ensures that mutexes are only used where needed, and not wasting time on unnecessary locking/unlocking for structures that are not shared. The locking/unlocking of protected structures slows down structures operations by about 7%. The `mutex()` function takes a second optional parameter denoting an existing mutex object or an object that is already marked as shared (has a mutex attribute) . Instead of creating a new mutex object for the data structure, the existing mutex is used as an attribute for the data structure. If the second object is a structure that is not marked as shared, a new mutex is created. This is useful when two objects need to be protected by the same mutex. For example, the list `L` and the table `T` in the following example share the same mutex:

```
mtx := mutex()
L := mutex([ ], mtx)
T := mutex(table(), mtx)
```

which is equivalent to the following if the mutex does not need to be explicit:

```
L := mutex([ ])
T := mutex(table(0), L)
or
L := [ ]
T := mutex(table(0), L)
```

In all cases, `lock(L)` and `lock(T)` lock the same mutex, serializing execution on both data structures. Not all operations on data structures produce correct results, only atomic operations do. In other words, implicit locking/unlocking takes place per operation, which means even if each one of the two operations is safe, the combination might not be. A critical region is still needed to combine the two. For example, if `L[1]` has the value of 3 and two threads are trying to increment `L[1]` as the following:

```
L[1] := L[1] + 1
```

the result in `L[1]` could be 4 or 5. That is because reading `L[1]` (the right side of the assignment) and storing the result back in `L[1]` are two different operations (not atomic) and are actually separated in time. The good news is that solving such an issue does not require an extra explicit mutex. If `L` is marked as shared (passed to the `mutex()` function ) it can be passed to `lock()/unlock()` functions. It can be used with the critical syntax like the following:

```
critical L: L[1] := L[1] + 1
```

### 32.2.2 Condition Variables

Mutexes protect shared data in critical regions, and block threads if more than one thread tries to enter the critical region. Condition variables provide thread blocking/resumption that is not tied to accessing shared data like a mutex. A condition variable allows a thread to block until an event happens or a condition changes. For example, in a producer/consumer problem, a consumer keeps spinning to get values out of the shared list. In similar situations in real life applications, any spinning could be a waste of resources; other threads including producer threads could be using the resources doing something useful instead. The consumer should block until there is data to process in the list. This is where a condition variable comes into play. A condition variable can be created using the function `condvar()`. The return object is a condition variable that can be used with `wait()` and `signal()` functions. `wait(cv)` blocks the current thread on the condition variable `cv`. The thread remains blocked until another thread does a `signal(cv)`, which wakes up one thread blocked on `cv`. A very important aspect of using a condition variable is that the condition variable is always associated with a mutex. More specifically, the `wait()` function has to be always protected by a mutex. Unicorn provides a built-in mutex for condition variables which can be thought of as an attribute, similar to thread safe data structures. This means a condition variable can also be used with `lock()/unlock()` functions or the critical clause. It is important to realize that not only `wait()` has to be protected by a critical region, but also the condition or the test that leads a thread to wait on a condition variable. The `signal()` function takes a second optional parameter denoting the number of threads to be woken up. By default, that number is one, but it can be any positive value. From example:

```
every !4 do signal(cv)
```

Can be written as:

```
signal(cv, 4)
```

Furthermore, if all of the threads waiting on `cv` needs to be woken up, a special 0 ( or `CV_BROADCAST`) value can be passed to `signal()` causing it to broadcast a wakeup call for all threads waiting on `cv`:

```
signal(cv, 0)
```

or

```
signal(cv, CV_BROADCAST)
```

## 32.3 Thread Communication

Co-expressions, as explained in [Chapter 3](#), have a simple form of communication influenced by their synchronous execution. Threads on the other hand, run in parallel, creating a dynamic environment for communication. In many cases, a running thread must send a value to another

thread without waiting for results, or receive a value from another thread if there is one without waiting. The @ operator is not suitable for this kind of (asynchronous) communication. Threads communication needs to go well beyond co-expressions, for which a single @ operator provided communication bundled with synchronization. Unicon adds four operators for asynchronous communication. These are @>, @>>, <@ and <<@. The operators correspond to send, blocking send, receive and blocking receive.

### 32.3.1 Thread messaging Queues

Thread communication is done through messaging queues that are initialized at thread creation. Each thread maintains two queues called the inbox and outbox that are created with the thread. When a thread sends a message with an explicit destination, the message is queued in the destination's inbox. Otherwise it is queued into the sender's outbox. A thread can receive messages from another thread by dequeuing messages from the source's outbox if there is an explicit source, otherwise it dequeues messages from its own inbox. [Figure 6.1](#) presents two threads with the inboxes and outboxes.

### 32.3.2 Send and Receive Operators

The first two operators are @> (send) and <@ (receive). These operators communicate send/receive messages between threads. The semantics support co-expressions as well which also have inboxes and outboxes. It does not matter whether threads or co-expressions are involved in the communication, the semantics are the same. The send operator has the syntax

$$x@>T$$

x can be any data type including null, which is equivalent to omitting it. T refers to a thread to which x is transmitted. x is placed in T's inbox. x can be picked by T using the receive operator which is presented later. The send operator can also have no destination such as:

$$x@>$$

In this case x is sent to no one, instead it is placed in the sender's outbox. The operator can be read as "produce x". x can then be picked up later by any thread wanting a value from this sender. For example the sender thread in this case might be a thread creating prime numbers and placing them in its outbox to be ready for other worker threads.

The receive operator is symmetric to the send operator and takes two forms, with explicit source or with no source as follows:

```
<@T
<@
```

The first case reads: receive a value from T, which gets a value from T's outbox, a value produced by T. Going back to the prime number example mentioned above, <@T would be the way to pick a prime number produced by the prime number generator thread T. <@ on the other hand reads values directly from the receiver's inbox. It reads messages sent directly to the current thread doing the receive. Both @> and <@ can succeed or fail. In the case of <@ the operator succeeds and returns a value from the corresponding queue (inbox/outbox) depending on the operand if the queue is not empty. If the queue is empty the operation fails directly. In the case of @>, if the value is placed in the corresponding queue, the operation succeeds and returns the size of the queue. If the queue is full, the send operation fails. The inbox/outbox for each thread is initialized to have a limited size (it can hold up to 1024 values by default). This limit can be increased or decreased depending on the application needs. The limits are useful so that queue sizes do not explode quickly by default and also to have an implicit communication/synchronization as explained later in this section.

Each thread has exactly one inbox and one outbox, and each operator call is mapped to only one of these inboxes or outboxes as seen in [Figure 1](#). All messages from all threads coming to thread B in the figure end up in its inbox. All threads trying to receive messages from A compete on its outbox. Both the inbox and the outbox queues are public communications channels, and it is impossible to distinguish the source of a message if there are several threads sending messages to the same thread at the same time. Furthermore, if <@ has an explicit source like A in [Figure 6.1](#) it only looks in A's outbox, and does not see messages from A coming directly to the inbox. Applications that require the sender's address can attach that information to messages by building them as records with two fields, one field for data and the other containing the sender's address. A better approach for private communications for some applications is the use of lists shared between the two communicating threads or the use of private communication channels discussed later in this chapter.

### 32.3.3 Inbox/Outbox and the `Attrib()` Function

As seen in previous subsections, communications between threads is done through inbox/outbox queues which are governed by size limits. The size limit (defaults to 1024) and the actual size dictate how synchronization is melted with the communication. The size operator \* can be used with a thread to query its actual outbox size (how many values it contains, not the maximum limit) and can be used as follows:

```
outbox_size := *T
```

But this is only a single attribute for one queue. To access or change the different attributes, a new function was introduced to Unicon: `Attrib()`, which uses the form:

`Attrib(handle, attribcode, value, attribcode, value, ...)`

The integer codes used by the `Attrib()` function are supplied by an include file (`threadh.icn`) with `$define` symbols for the attributes. This header file is part of a new thread package that is part of the Unicon distribution called package threads. It can be imported to a program via:

```
import threads
```

When values are omitted, `Attrib()` generally returns attribute values. To get the size of the outbox (similar to what the `*` operation does in the example presented earlier), the code is:

```
outbox_size := Attrib(T, OUTBOX_SIZE)
```

similarly,

```
inbox_size := Attrib(T, INBOX_SIZE)
```

gets the current size of the inbox. On the other hand,

```
Attrib(T, INBOX_LIMIT, 64, OUTBOX_LIMIT, 32)
```

sets the inbox and outbox size limits to 64 and 32 respectively. Table 6.1 summarizes all of the available attributes and their meanings.

Attribute	Meaning	Read/Write
INBOX_SIZE	Number of items in the inbox	Read Only
OUTBOX_SIZE	Number of items in the outbox	Read Only
INBOX_LIMIT	The maximum number of items allowed in the inbox	Read/Write
OUTBOX_LIMIT	The maximum number of items allowed in the outbox	Read/Write

**Table 6.1** Thread's communication queues attributes

### 32.3.4 Blocking Send and Receive

In many situations, senders and receivers generate and consume messages at different speeds. For example if there is thread that generates prime numbers very fast to be used by other slow threads, the prime number generator thread should not continuously generate prime numbers, but create a batch and wait until it is all used before generating another batch. Instead of overloading slow receivers or busy waiting for slow senders, the two ends of communication require a synchronizing mechanism to tell when to send new messages or when a new message is available. Two more send and receive operators provide such functionality, these are the blocking send operator `@>>` and the blocking receive operator `<<@`. These operators can be used in the same way `@>` and `<@` are used, except that instead of failing when the operation cannot be completed, the new operators block and wait until the operation succeeds. This is useful in situations where a value is required to proceed, allowing the thread to block instead of spinning waiting for a value.

In some cases, a thread might want to use a blocking receive to get values from a second thread, but it is not willing to block indefinitely; probably the thread can do some other useful work instead of waiting. The `<<@` accepts a timeout parameter to impose a limit on how long to wait for a result before giving up. Here is how `<<@` would look like in this case:

result := timeout <<@ # get from the current thread inbox

or

result := timeout <<@ T # get from T's outbox

The timeout operand is a non-negative integer denoting the maximum time to wait in milliseconds. Negative integers are treated as a null value, an indefinite blocking receive. A 0 operand indicates no waiting time, making the end behavior effectively similar to a non-blocking receive.

Table 6.2 summarizes the different forms of the send and receive operators and their operands:

Table 6.2 Summary of the new communication operators

Operator	Operands	Behavior
@>		(send)
msg@>		Place msg in the current thread's outbox, fail if the outbox is full
msg@>T	T	Place msg in T's inbox, fail if T's inbox is full
<@		(receive)
<@		Get a message from the current thread's inbox, fail if it is empty
<@T	T	Get a message from T's outbox, fail if T's outbox is empty
@»		(blocking send)
msg@»		Place msg in the current thread's outbox, block if the outbox is full
msg@»T	T	Place msg in T's inbox, block if the T's inbox is full
«@		(blocking receive)
«@		Get a message from the current thread's inbox, block if it is empty
«@T	T	Get a message from T's outbox, block if T's outbox is empty
n«@		Get a message from the current thread's inbox, block up to n milliseconds if the inbox is empty waiting for new messages
n«@T	T	Get a message from T's outbox, block up to n milliseconds if T's outbox is empty waiting for new messages to become available

## 32.4 Virtual Machine Changes

The Unicon virtual machine is the Icon virtual machine, extended to better accommodate object-oriented programming. The extensions made to support true concurrency would apply equally to the Icon implementation. Other similar languages face analogous situations, where the lessons learned here may be applicable. Two main issues had to be addressed in order to allow concurrent execution of multiple threads in the VM. First, the VM's state had to be replicated per thread, and second, self-modifying instructions and the initial clause had to be protected against race conditions. The two issues are discussed in the following two subsections.

### 32.4.1 VM Registers

Thread-local storage is utilized to provide each thread with its own copy of the virtual machine registers, which were formerly global variables in the VM C code. These include the program counter, stack pointer, the several frame pointers necessary to manage calls, returns, suspension and resumption on the stack, and other pieces of virtual machine state. To add concurrency, these elements of state are moved into a struct `threadstate` that is allocated for each thread, and keeps all thread-specific VM state information. The `threadstate` is fairly large, under the assumption that memory is cheap whereas thread synchronization is expensive. POSIX threads API calls are used to obtain references to the `threadstate` structure where it is needed. A key concern when using thread-local storage is performance. Initially, all references to VM registers were replaced, via macros, by references through a global `threadstate` pointer variable declared with the compiler storage specifier `__thread` that is available in some compilers such as gcc and Sun's (now Oracle's) cc. This implementation is straightforward but incurs a substantial performance cost. In addition, the `__thread` keyword is not currently available in the pthreads implementation on OS X and that of Mingw gcc on Microsoft Windows. Switching to the more portable pthreads API for thread-local storage using `pthread_getspecific()` allows a faster implementation than `__thread`. The straightforward implementation invoked `pthread_getspecific()` once at the top of each C function containing references to VM register and state variables. The many calls to this API wherever the VM state is referenced in the runtime system entail an insignificant performance cost.

### 32.4.2 Self-Modifying Instructions

The Unicon virtual machine has seven instructions that contain integer offsets as operands. These offsets refer to memory addresses within the instruction region, or to static data regions of the bytecode. They are used for several types of literals, globals, static variables, and also for instructions that jump to addresses, such as `Op_Goto`. For performance reasons, when the opcode is first encountered, offsets are converted to absolute pointers. The opcode is modified to indicate that the operand is now a pointer, and the instruction proceeds at full speed on subsequent executions.

This implementation introduces a race condition when multiple threads execute the self-modifying instruction at the same time. The problem was solved by adding a mutex for each self-modifying instruction opcode. [Figure 6.2](#) shows an example self-modifying instruction code protected with a mutex. Mutex contention could be reduced further by allocating a separate mutex for each instance of each opcode (requiring a number of mutexes proportional to the size of the program) instead of using just seven mutexes for the seven self-modifying opcodes; it is unlikely that this would be worth implementing, since the number of instances is large and each instance of a self-modifying instruction uses its mutex only once when it replaces itself. To provide a thread safe initial clause (discussed in [6.1.2](#)) at the language level, a similar technique used for self-modifying instructions was utilized, unlike self-modifying instructions, where locking and unlocking take place at the same instructions, with initial clause, the locking happens at the beginning of the clause, and the unlocking happens at the end. To allow such behavior, a new VM instruction was introduced which takes care of updating the instruction at the beginning of the clause, and unlocks the mutex. The updated instruction causes all of the subsequent calls to the function containing the initial clause made by any thread to skip over the clause. This mechanism effectively eliminates the need to do any locking/unlocking after it is initialized.

### 32.4.3 Runtime System Support

Achieving thread-safety in the implementation without a global interpreter lock required extensive modifications to the runtime system to provide a thread-safe environment. This includes safe use of the IO subsystem and the underlying libraries, but most importantly heap management in term of allocation and garbage collection.

#### 32.4.3.1 Input/Output Sub-system

The Unicon input output sub-system includes very high-level facilities for accessing files, networks and messaging, 2D and 3D graphics, databases, pipes and pseudo-ttys. The underlying C library functions implementing these capabilities are often thread- safe [96]. However, Unicon language-level IO operations usually involve several underlying library calls that must be atomic with respect to threads. Each IO handle is assigned a mutex when it is opened. Any IO operation that uses this handle locks the mutex to guarantee the atomicity of such operations. The cost incurred by such locks is evaluated in [section 7.4](#). The atomicity of IO is guaranteed only within a single Unicon-level IO operation. For example `write(x, y)` is atomic and no other thread can write to the same file while `write()` is running. If multiple writes or reads are required to be made atomic with respect to other threads, an explicit lock is needed. In such a case, the IO handle can be passed to the `lock()/unlock()` functions to protect it from any access other than from the current thread during the execution of several IO operations.

### 32.4.3.2 C Library Thread Safety

In addition to IO, many C library functions called in the Unicon VM were implemented before threads were widely used in operating systems. A subset of those functions is documented in the POSIX standards as thread-unsafe. About 40 of these function were used in the runtime system. Most calls to these thread-unsafe functions were replaced with the thread-safe alternatives available in modern C implementations. A few, infrequently called, thread-unsafe functions were protected by mutexes. A couple of the thread-safe alternatives were not portable; new wrapper functions or implementations were developed in such cases.

### 32.4.3.3 Allocation and Separate Heaps

Allocation is a frequent operation for which speed is a top priority in the Unicon virtual machine. Unicon programs start with a heap consisting of one string and one block (structure) region, and allocate more regions as needed. At any moment, the string and block regions used for allocation are together referred to as the current heap. If the memory request is bigger than what is available in the current heap, other regions are checked. If enough memory is found, the current heap is switched to use the satisfying region; otherwise a new region is allocated. With multiple threads, safety becomes a concern if only one shared heap is available. When a thread allocates memory in the current heap and updates the heap's state variables, the operation must be protected by a mutex. Otherwise different threads would corrupt each other's allocation requests, leaving the heap in an invalid state. A similar situation occurs when some operations in the runtime system deallocate memory after allocating it for a temporary use.

After determining that the locks required in the shared heap strategy were significantly slowing down the frequent task of memory allocation, the decision was made to use separate, per-thread heaps. This allows threads to use their own private heaps at full speed, just like a single-threaded application. Heaps that are not owned by any thread are referred to as public heaps. Public heaps are a product of threads out-growing their private heaps. This happens when a thread requests more memory and that request can only be granted by allocating a new private heap. A program starts with no public heaps, and with one private heap for the main thread. A new private heap is allocated for each new thread if none of the public heap is sufficient. **Figure 6.3** shows the heap layout with regards to threads. when a thread finishes, its heap goes back to the pool of public heaps.

All heaps (public and private) are visible to all threads, so any thread can access variables and data structures in any heap at any time. The accesses can be controlled or protected at the application level, if needed, in the case of a shared variable. The terms private and public heaps here are limited to allocating memory in the heaps, and are not to be confused with memory access to heaps in general. In other words, a thread can allocate memory only in its private heap, but can access (read and write) variables in all heaps. Having a full private heap does not mean a thread will automatically allocate a new fresh heap. When a memory request cannot be granted in the private heap, public heaps are checked to see if any of them has enough free memory to grant the request.

If so, the private heap is swapped with the public heap, changing the private heap to public and vice-versa. The pool of public heaps is protected by a mutex. If public heaps do not have enough free memory, a garbage collection will take place. If the memory request cannot be granted even after that, the thread allocates a fresh heap.

### 32.4.4 Garbage Collection

The frequency of garbage collection depends on heap size and application memory usage patterns. Historically, many Icon applications ran to completion without ever garbage collecting. However, modern object oriented event-driven applications run for longer periods of time, and garbage collect proportionally often, despite increases in physical memory and heap size. When garbage collection does occur, it concerns every thread. Since garbage collection does not happen often (examples are given in [Chapter 9](#)), the design philosophy is to keep garbage collection as simple as possible under concurrent execution. To allow safe access to data in the heaps, garbage collection suspends all running threads except the thread which triggered it, referred to as the GC thread. The GC thread performs a conventional garbage collection, during which the program runs sequentially.

The GC thread first locks the garbage collection mutex `MTX_THREADCONTROL`, and then sets a global flag that announces the need to perform garbage collection. It directs all running threads to converge to a special routine called `thread_control`, the coordination point for thread suspension and resumption. The global flag is checked by all threads once per virtual machine instruction. The runtime system keeps track of how many threads are running using a global counter `NARthreads`, which is incremented and decremented by the threads depending on their state: before a thread blocks on a mutex it decrements the counter, and increments it after unblocking. The counter itself is protected by a mutex and can be incremented only if there is no garbage collection request pending or taking place ([Figure 6.4](#)).

After a call for garbage collection causes a thread to enter the `thread_control` function, the thread decrements the running threads counter `NARthreads` and goes to sleep on the `gc` condition variable. The GC thread keeps testing the running threads counter until its value decreases to 1, meaning that the GC thread is the only thread running. Then the GC thread proceeds to perform the garbage collection. After finishing, the GC thread unlocks the garbage collection mutex, and does a broadcast to the `gc` condition variable. This wakes up all of the threads blocked on the `gc` variable, allowing them to resume their execution and return to where they called the `thread_control` function in the first place.

In garbage collection-intensive applications, it may happen that two (or more) threads trigger a garbage collection at the same moment. This situation can be handled in various ways. The simplest solution is to block all of the threads requesting garbage collection after the first one and let the first one proceed and finish as described above (block all of the other threads and then wake them up again). A better solution, the one adopted in this design, is to make the threads that are competing for garbage collection aware of each other. Instead of a sequence of block all others

followed by a wake up others performed by each GC thread, a GC thread can hand the control over to the next GC thread in line, if there is one, and then go to sleep. Only the last GC thread in the line wakes up all of the blocked threads. This strategy eliminates intermediate block/wakeup operations, leaving only one block others operation by the first GC thread and one wake up others operation by the last GC thread. A counting semaphore (gc semaphore) controls the queuing and synchronizing of several threads to garbage collect. The first thread to request a garbage collection does not block on the semaphore, but subsequent requesters do. After finishing garbage collection, each thread signals the semaphore to wake up the next GC thread and goes to sleep. The last GC thread to wake up is responsible for waking up all of the threads after finishing.

An additional measure increases the effectiveness of the strategy just described: triggering an artificial garbage collection if another thread has a garbage collection request pending. After a thread triggers a garbage collection and starts the protocol to suspend all other threads, each thread answers the call, but before going to sleep on the gc condition variable it checks if its heap is nearly full. The nearly full value depends on the heap size, the number of threads, and the nature of the application. Tests indicate that generally, a value in the range 90%-95% is reasonable for most applications (garbage collection example statistics are given in [Table 9.1](#) ). Thus if the threads heap has only 5%-10% of its total size free, the thread queues up to do garbage collection instead of going to sleep on the gc condition variable. This technique forces several garbage collections that might be separated by very short periods of time to cluster together, requiring only a single suspension for all of the threads to do the several garbage collections. [Figure 6.5](#) shows an abstract overview of garbage collection and concurrency control.

# Chapter 33

## Execution Monitoring

This chapter describes the implementation of program execution monitoring facilities in Unicon. Prior to these facilities, some simple monitors of Icon programs had been written in C, using instrumentation that was added to generate log files from the C implementation of Icon's virtual machine, `iconx`. Development of these tools in C was too labor intensive for experimental research work. The primary goal of the monitoring facilities is to allow monitors for Icon and Unicon to be written in Unicon instead of C.

The monitoring facilities were added by writing a dynamic loader for Icon icode and extending the co-expression data type to allow the loading and execution of programs as co-expressions within the same virtual machine. This was considered viable to achieve high performance, since the co-expression switch was frequently and publically extolled by Ralph Griswold as being very high performance (comparable to a procedure call in Icon), while transmitting monitoring information to a separate process via pipes, sockets or any other means that would require operating system synchronization was considered too expensive.

Since that time, the co-expression type has gotten much slower in Icon, whose current implementation has eliminated native assembler co-expressions in favor of a portable pthreads implementation and removed the monitoring facilities entirely. In Unicon, the monitoring facilities remain a compelling reason to retain native co-expressions indefinitely, since they constitute the core of the Unicon debugger `udb`, and the profiler `uprof`.

### 33.1 Dynamic Loading and the Program State

Several major changes were required in order to support multiple programs in the virtual machine. Loading the icode into a separate malloced area was the easy part. Numerous global and/or static C variables contained program-specific state – on an abstract level they could be considered “registers” of the Icon virtual machine. In practice, they must be saved/restored whenever switching between programs, and it was quickly found that they were too numerous to easily save and restore: switch-

ing time would be too slow. Instead, these variables were all moved into a new structure, and a pointer to this structure became the one variable that needed to be saved/restored whenever switching between programs. The variable was named `curpstate` and the structure in `src/h/rstructs.h` looks like:

```

/*
 * Program state encapsulation. This consists
 * of the VARIABLE parts of many global structures.
 */
struct progstate {
    long hsize; /* size of icode */
    /* hsize is a constant defined at load time, MT safe */
    struct progstate *parent;
    /* parent is a constant defined at load time, MT safe */
    struct progstate *next;
    /* next is a link list, seldom used, needs mutex */
    struct descrip parentdesc; /* implicit &parent */
    /* parentdesc is a constant defined at load time, MT safe */

```

## 33.2 Event Instrumentation, Filtering and Reporting

Interesting behavior within the Unicon virtual machine is instrumented using macros. Originally the macros were defined as no-ops or as output statements that would write to logfiles. In the monitoring facilities, the macro can instead be defined to check whether that event has been requested by a monitor, and if so, to report that event.

The monitoring macros began with clean and simple form. They have been elaborated many times and are now more subtle. Originally the macros consisted of

```

#define EVVal(value,event) ...
#define EVValD(dp,event) ...

```

where EVVal() reported an integer event value while EVValD() took a descriptor pointer and reported an arbitrary value. The second argument in both cases was the event code, an integer indicating what was happening. These macros live in src/h/grttin.h where they are automatically included in every compile by the rtt program.

### 33.2.1 Filtering: Event Masks and Value Masks

If all events were reported to the monitor, it would have complete information but be overwhelmed. Filtering of desired events was essential from the beginning, and was refined over time from a single level to a two-level process.

Event codes of interest are specified by monitors using an event set. Since the event codes are all in the range 0-255, the most efficient representation of these sets is by means of a bit vector, and the most convenient bit vector implementation already available was the cset data type. Initially, then, the definitions of EVVal() and EVValD() looked something like

```
#define EVVal(value,event) \
    if (Testb((word)ToAscii(event)), curpstate->eventmask) { \
        MakeInt(value, *(curpstate->parent->eventval)); actparent(event); }
```

Event masks are csets, with individual characters ASCII values indicating which event they denote. Testb() is the internal cset membership test operation. If the event is of interest (i.e. in the program's event mask, set by a monitor), it is reported by placing its value in the parent (monitor) &eventvalue and calling actparent() to activate and switch control to the parent, thus accomplishing an event report.

Many of the event codes started with mnemonics, such as P for "procedure call". Over time, mnemonics proved unhelpful and all events were in fact re-ordered at some point for efficiency purposes, such that events must be referred to by symbolic names associated with their unsigned char integer codes. These names are in src/h/monitor.h and all begin with the prefix E\_, as in E\_Pcall for "procedure call event".

Event masks were essential in creating run-time monitoring facilities, but in certain cases, even more filtering is needed. For example, the event for virtual machine instructions is extremely frequent. An additional layer of filtering was introduced in the form of value masks, such that for each event code in the event mask, a (Unicon) set of values of interest could be specified. The macro became so long that it was preferable to use rtt's multi-line macro syntax (#begdef...#enddef). With value mask tests in place the EVVal() macros look more like:

```
#begdef RealEVVal(value,event,exint,entint)
do {
    if (is:null(mycurpstate->eventmask)) break;
    else if (!Testb((word)ToAscii(event), mycurpstate->eventmask)) break;
    MakeInt(value, &(mycurpstate->parent->eventval));
    if (!is:null(mycurpstate->valuemask) &&
        (invaluemask(mycurpstate, event, &(mycurpstate->parent->eventval))
            != Succeeded))
        break;
    exint;
    actparent(event);
    entint;
} while (0)
#enddef /* RealEVVal */
```

The reason that these macro definitions are prefixed “Real” is that they can in turn be enabled or disabled on a per-eventcode basis via

```
#ifndef EVVal(value,event)
#define EVVal(value,event,/*noop*/,/*noop*/)
#endif
#endif /* EVVal */
```

This is probably overkill.

### 33.3 Instrumented vs. Uninstrumented Run-time Functions

In Icon, the pervasive instrumentation of run-time events was seen to cost about 50% performance, even when not in use. For this reason a separate copy of the iconx virtual machine was built specifically for monitoring, an miconx. It was workable but inconvenient to be shipping an extra copy of the VM executable for monitoring purposes; it took up extra space, and complicated the build makefile.

For Unicon, a scheme was devised to compile both the instrumented and full-speed uninstrumented versions of the 30 runtime functions that had events in them. For each such function, say `cnv_str()` for example, the body of the function is placed in a macro that is instantiated twice, once with events and once without. The macro is parameterized by the event codes that that function has instrumented within it and is capable of producing:

```
#ifndef cnv_str_macro(f, e_aconv, e_tconv, e_nconv, e_sconv, e_fconv)
/*
 * cnv_str - cnv:string(*s, *d), convert to a string
 */
int f(dpstr s, dpstr d)
{
    ...
}
#endif
#ifdef MultiThread
#define cnv_str_macro(f, e_aconv, e_tconv, e_nconv, e_sconv, e_fconv)
cnv_str_macro(f, e_aconv, e_tconv, e_nconv, e_sconv, e_fconv)
#else /* MultiThread */
#define cnv_str_macro(f, e_aconv, e_tconv, e_nconv, e_sconv, e_fconv)
cnv_str_macro(f, e_aconv, e_tconv, e_nconv, e_sconv, e_fconv)
#endif /* MultiThread */
```

So the definition of `cnv_str` accomplishes the definition of an instrumented `cnv_str_1` as a by-product. In the current implementation, instrumentation of a given function is an all-or-nothing decision. The macros are capable of supporting multiple, finer-grained instantiations with partial instrumentation, if desired.

Whether to use the instrumented or uninstrumented version of each of these functions is decided at runtime on a per-program basis and can change over time. Which functions are in use are specified by a set of function pointers in the current program state structure. These function pointers are calculated based on the program's event mask. Whenever the event mask changes, the set of instrumented functions is recalculated; this is normally during `EvGet()` and lives in a function named `assign_event_functions()`.

```
void assign_event_functions(struct progstate *p, struct descrip cs)
{
    p->eventmask = cs;

    /*
     * Most instrumentation functions depend on a single event.
     */
    p->Cplist =
        ((Testb((word)ToAscii(E_Lcreate), cs)) ? cplist_1 : cplist_0);
```

Using function pointers in the program state instead of direct function calls for these 30 common functions in the Unicon virtual machine imposes a cost on runtime performance due to added indirect memory references performed during those calls. The cost was measured and believed to be under 5% at the time it was introduced, which was considered acceptable for the added capabilities and convenience of having monitoring available and standard within the regular Unicon virtual machine.

# **Part IV**

## **Appendices**

# Appendix A

## Data Structures

This appendix summarizes, for reference purposes, all descriptor and block layouts in Icon and Unicon. [Unicon adds extra fields to many structures in order to manage concurrent threads and to provide mutual exclusion between threads. These extra fields are drawn in blue.](#)

### A.1 Descriptors

Descriptors consist of two words (normally C ints): a d-word and a v-word. The d-word contains flags in its most significant bits and small integers in its least significant bits. The v-word contains a value or a pointer. The flags are

- n      nonqualifier
- p      v-word contains a pointer
- v      variable
- t      trapped variable

#### A.1.1 Values

There are three significantly different descriptor layouts for values. A qualifier for a string is distinguished from other descriptors by the lack of an n flag in its d-word, which contains only the length of the string. For example, a qualifier for the string "hello" is

The null value and (small) integers have type codes in their d-words and are self-contained. Examples are:

For all other data types, a descriptor contains a type code in its d-word and a pointer to a block of data in its v-word. A record is typical:

### A.1.2 Variables

There are two formats for variable descriptors. The v-word of an ordinary variable points to the descriptor for the corresponding value:

If the variable points to a descriptor in a block, the offset is the number of *words* from the top of the block to the value descriptor. If the variable points to a descriptor that corresponds to an identifier, the offset is zero.

The descriptor for a trapped variable contains a type code for the kind of trapped variable in its d-word and a pointer to the block for the trapped variable in its v-word. The trapped variable may either be a substring or a table element. Both are drawn in section A.2.9.

## A.2 Blocks

With the exception of the null value, integers, and strings, the data for Icon values is kept in blocks. The first word of every block is a title that contains the type code for the corresponding data type. For blocks that vary in size for a particular type, the next word is the size of the block in bytes. The remaining words depend on the block type, except that all non-descriptor data precedes all descriptor data. With the exception of the long integer block, the diagrams that follow correspond to blocks for computers with 32-bit words.

### A.2.1 Long Integers

An Icon integer that fits in the v-word is stored there. An integer that is too large to fit into a word is stored in a block that is pointed to by the v-word. The two representations of integers are distinguished by different internal type codes: *integer* for integers that are contained in the v-words

of their descriptors and `lrgint` for integers that are contained in blocks pointed to by the v-words of their descriptors. Thus, there are two internal types for one source-language data type.

### A.2.2 Real Numbers

Real numbers are represented by C doubles. For example, on computers with 32-bit words, the real number 1.0 is represented by

### A.2.3 Csets

The block for a cset contains the usual type code, followed by a word that contains the number of characters in the cset. Words totaling 256 bits follow, with a one in a bit position indicating that the corresponding character is in the cset, and a zero indicating that it is not. For example, `&ascii` is

A.2.4 Lists

A list consists of a list-header block that points to a doubly-linked list of list-element blocks, in which the list elements are stored in circular queues. See Chapter 6 for details. An example is the list

[1,2,3]

which is represented as

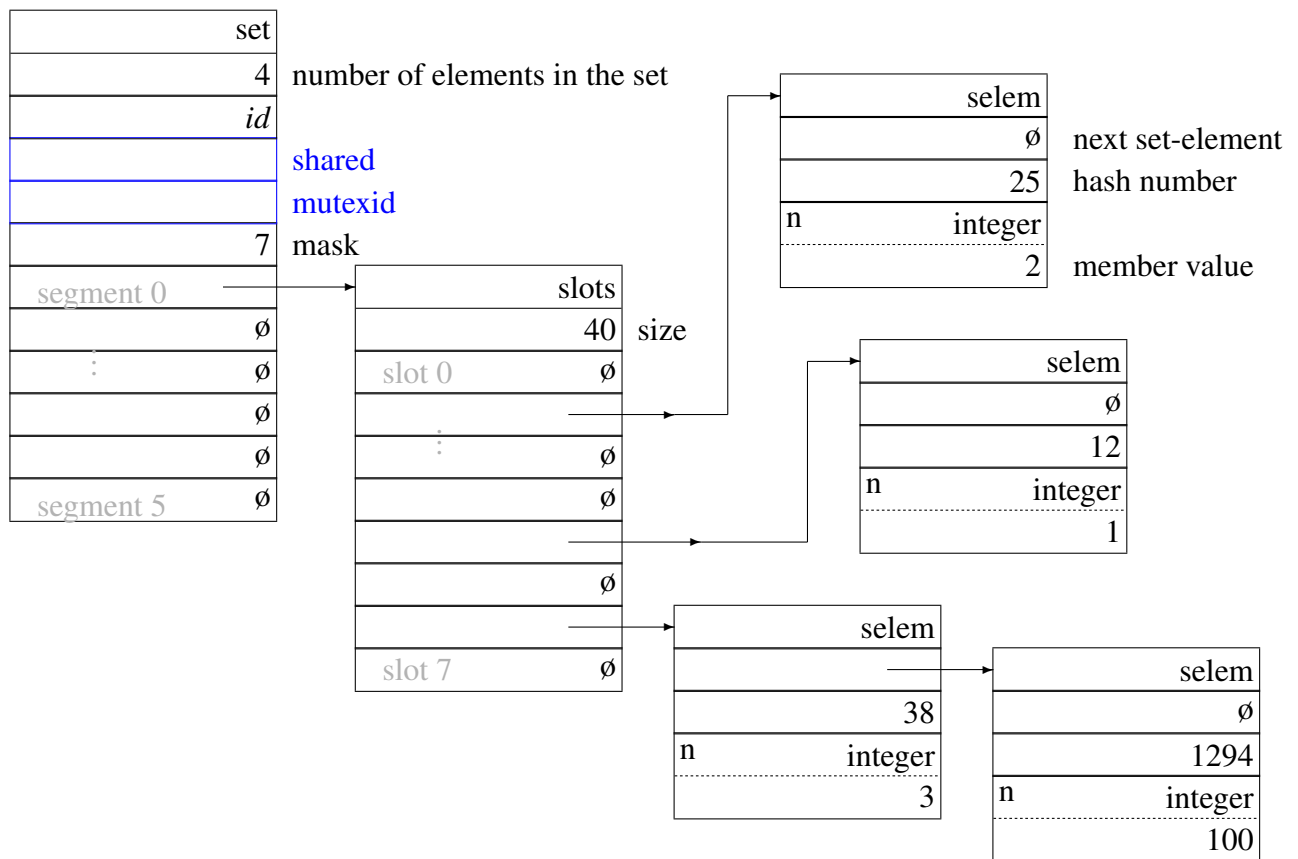

Here there is only one list-element block:

## A.2.5 Sets

A set consists of a set-header block that contains segments that point to blocks containing slots for linked lists of set-element blocks. A set header must be a proper prefix of a table header, and a set element must be a proper prefix of a table element. See Sec. 7.1 for details. An example is given by

`set([100, 1, 2, 3])`

which is represented as

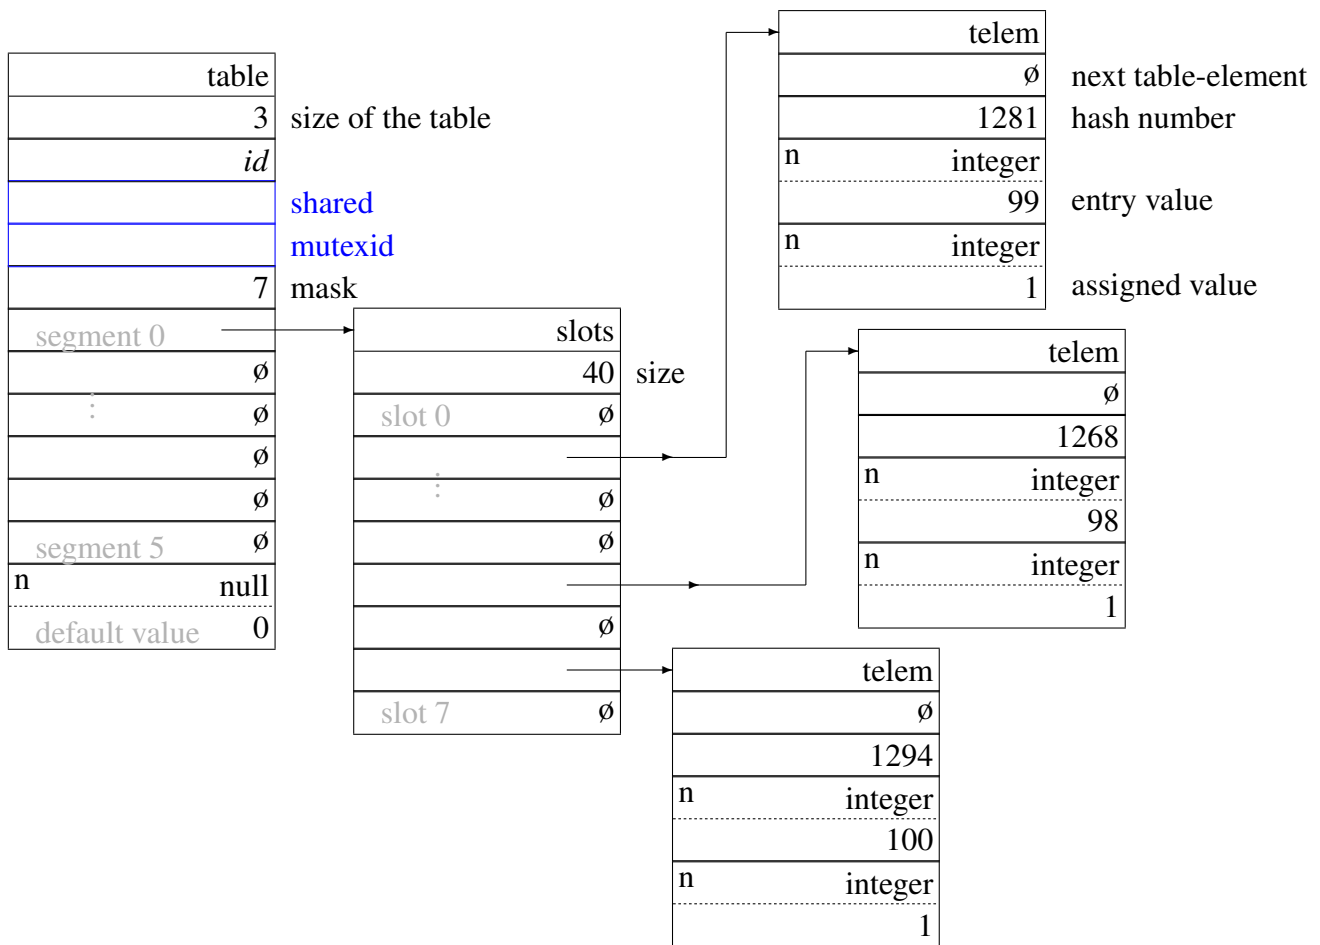

## A.2.6 Tables

A table is similar to a set, except that a table-header block contains the default assigned value as well as slots for linked lists of table-element blocks. See Sec. 7.2 for details. An example is given by

`t := table()`  
`every t[98 to 100] := 1`

The table `t` is represented as

### A.2.7 Procedures

The procedure blocks for procedures and functions are similar. For a procedure declaration such as

```

procedure calc(i,gj)
  local k
  static base, index
  ⋮
end

```

the procedure block is

proc	
80	size of block
—	→ initial ipc
2	number of arguments
1	number of local identifiers
2	number of static identifiers
0	index of first static identifier
—	→ file name
4	
—	→ "calc"
1	
—	→ "i"
1	
—	→ "j"
1	
—	→ "k"
4	
—	→ "base"
5	
—	→ "index"

In a procedure block for a function, there is a value of -1 in place of the number of dynamic locals. For example, the procedure block for repl is

proc	
40	size of block
—	→ C entry point
2	number of arguments
-1	function indicator
0	not used
0	not used
0	not used
4	
—	→ "repl"

In the case of a function, such as write, which has a variable number of arguments, the number of arguments is given as -1:

proc	
40	size of block
—	→ C entry point
-1	indicator of a variable number of arguments
-1	function indicator
0	not used
0	not used
0	not used
5	
—	→ "write"

**A.2.8 Files**

The block for a file contains a pointer to the corresponding file, a word containing the file status, and a qualifier for the name of the file. For example, the block for &output is

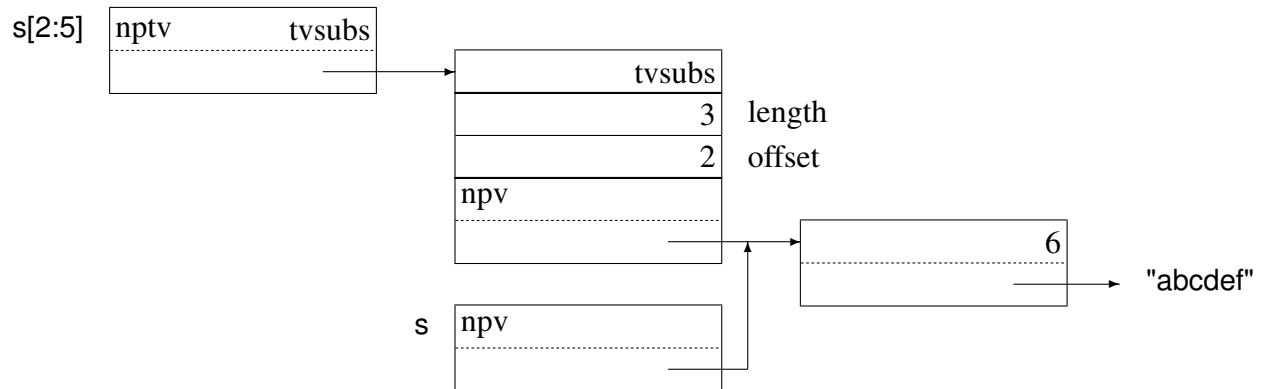

The file status values are

- 0 closed
- 1 open for reading
- 2 open for writing
- 4 open to create
- 8 open to append
- 16 open as a pipe

**A.2.9 Trapped Variables**

There are two kinds of trapped variables: substring trapped variables, and table-element trapped variables. The corresponding blocks are tailored to the kind of trapped variable.

A substring trapped variable contains the offset and length of the substring, as well as a variable that points to the qqualifier for the string. For example, if the value of s is "abcdef", the substring trapped-variable block for s[2:5] is

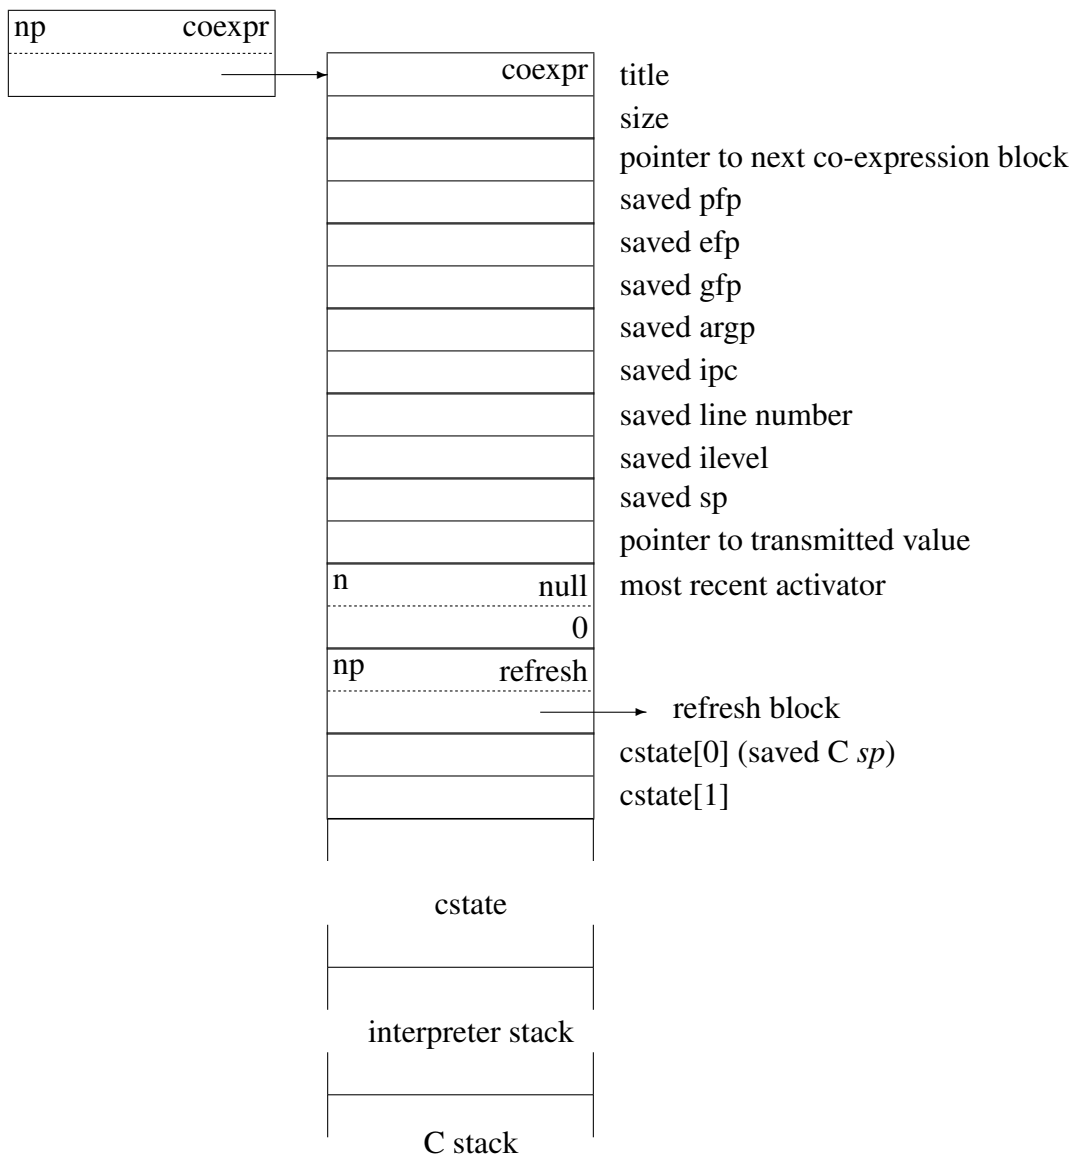

A table-element trapped-variable block contains a word for the hash number of the entry value, a pointer to the table, the entry value, and a descriptor reserved for the assigned value. For example, if `t` is a table, the table-element trapped-variable block for `t[36]` is

### A.2.10 Co-Expressions

A co-expression block consists of heading information, an array of words for saving the C state, an interpreter stack, and a C stack:

The refresh block contains information derived from the procedure block for the procedure in which the co-expression was created. Consider, for example,

```

procedure labgen(s)
  local i, j, e
  i := 1
  j := 100
  e := create (s || (i to j) || ":")
  :
end

```

For the call `labgen("L")`, the refresh block for `e` is

	refresh	title
	88	size of block
		initial ipc
	3	number of local identifiers
		saved number of arguments
		saved pfp
		saved efp
		saved gfp
		saved argp
		saved ipc
		saved line number
		saved ilevel
n	proc	value of labgen
		→ procedure block
	1	value of s
		→ "L"
n	null	value of i
	1	
n	integer	value of j
	100	
n	null	value of e
	0	

# Appendix B

## Virtual Machine Instructions

This appendix lists all the Icon and Unicon virtual machine instructions. For instructions that correspond to source-language operators, only the corresponding operations are shown. Unless otherwise specified, references to the stack mean the interpreter stack. If  $j > i$  then  $expr_j$  is closer to the top of the stack than  $expr_i$  (i.e.  $expr_j$  will be popped before  $expr_i$ ).

Instructions coloured in blue have been added to the Unicon virtual machine.

acset a	Push a descriptor for the cset block at address a onto the stack.
aglobal a	Push a variable descriptor pointing to global identifier at address a onto the stack.
agoto a	Set ipc to address a.
amark a	Create an expression frame whose marker contains the failure ipc corresponding to the address a, the current efp, gfp, and ilevel.
apply	$expr_1 ! expr_2$
areal a	Push a descriptor for the real number block at address a onto the stack.
arg n	Push a variable descriptor pointing to argument n.
asgn	$expr_1 := expr_2$
astatic a	Push a variable descriptor pointing to static identifier at address texttta.
astr n, a	Push a descriptor for the string of length n at address a.
bang	$!expr$

bscan	Push the current values of &subject and &pos. Convert the descriptor prior to these two descriptors into a string. If the conversion cannot be performed, terminate execution with an message. Otherwise, assign it to &subject and assign 1 to &pos. Then suspend. If resumed, restore the former values of &subject and &pos and fail.
cat	$expr_1 \parallel expr_2$
ccase	Push a copy of the descriptor just below the current expression frame.
chfail n	Change the failure ipc in the current expression frame marker to n.
coact	Save the current state information in the current co-expression block, restore state information from the co-expression block being activated, perform a context switch, and continue execution.
cofail	Save the current state information in the current co-expression block, restore state information from the co-expression block being activated, perform a context switch, and continue execution with co-expression failure signal set.
compl	$\sim expr$
coret	Save the current state information in the current co-expression block, restore state information from the co-expression block being activated, perform a context switch, and continue execution with co-expression return signal set.
create	Allocate a co-expression block and a refresh block. Copy the current procedure frame marker, argument values, and local identifier values into the refresh block. Place a procedure frame for the current procedure on the stack of the new co-expression block.
cset a	Push a descriptor for the cset block at icode offset a onto the stack. Becomes opcode acset on subsequent executions.
diff	$expr_1 \text{ -- } expr_2$
div	$expr_1 / expr_2$
dup	Push a null descriptor onto the stack and then push a copy of the descriptor that was previously on top of the stack.

efail	If there is a generator frame in the current expression frame, resume its generator. Otherwise remove the current expression frame. If the ipc in its marker is nonzero, set ipc to it. If the failure ipc is zero, repeat efail.
einit	end of initial section. In concurrent VMs, change the init instruction to a goto here.
eqv	$expr_1 === expr_2$
eret	Save the descriptor on the top of the stack. Unwind the C stack. Remove the current expression frame from the stack and push the saved descriptor.
escan	Dereference the top descriptor on the stack if necessary. Copy it to the place on the stack prior to the saved values of &subject and &pos (see bscan). Exchange the current values of &subject and &pos with the saved values on the stack. Then suspend. If resumed, restore the values of &subject and &pos from the stack and fail.
esusp	Create a generator frame containing a copy of the portion of the stack that is needed if the generator is resumed.
field n	Replace the record descriptor on the top of the stack by a descriptor for field n of that record.
global n	Push a variable descriptor pointing to global identifier n. Becomes opcode aglobal on subsequent executions.
goto n	Set ipc to offset n. Becomes opcode agoto on subsequent executions.
init n	Change init instruction to goto. <a href="#">Concurrent VMs impose mutual exclusion at this point.</a>
int n	Push a descriptor for the integer n.
inter	$expr_1 ** expr_2$
invoke n	$expr_0(expr_1, expr_2, \dots, expr_n)$
keywd n	Push a descriptor for keyword n.
lconcat	$expr_1     expr_2$
lexeq	$expr_1 == expr_2$

lexge	$expr_1 \geq expr_2$
lexgt	$expr_1 > expr_2$
lexle	$expr_1 \leq expr_2$
lexlt	$expr_1 < expr_2$
lexne	$expr_1 \neq expr_2$
limit	Convert the descriptor on the top of the stack to an integer. If the conversion cannot be performed or if the result is negative, terminate execution with an error message. If it is zero, fail. Otherwise, create an expression frame with a zero failure ipc.
line n	Set the current line number to n.
llistn	$[expr_1, expr_2, \dots, expr_n]$
localn	Push a variable descriptor pointing to local identifier n.
lsusp	Decrement the current limitation counter, which is immediately prior to the current expression frame on the stack. If the limit counter is nonzero, create a generator frame containing a copy of the portion of the interpreter stack that is needed if the generator is resumed. If the limitation counter is zero, unwind the C stack and remove the current expression frame from the stack.
mark	Create an expression frame whose marker contains the failure ipc corresponding to the label n, the current efp, gfp, and ilevel.
mark0	Create an expression frame with a zero failure ipc.
minus	$expr_1 - expr_2$
mod	$expr_1 \% expr_2$
mult	$expr_1 * expr_2$
neg	$-expr$
neqv	$expr_1 \equiv expr_2$
nonnull	$\backslash expr$

noop	Do nothing. Allows insertion of labels at certain points. Can be optimized away.
null	$/expr$
number	$+expr$
numeq	$expr_1 = expr_2$
numge	$expr_1 \geq expr_2$
numgt	$expr_1 > expr_2$
numle	$expr_1 \leq expr_2$
numlt	$expr_1 < expr_2$
numne	$expr_1 \neq expr_2$
pfail	If &trace is nonzero, decrement it and produce a trace message. Unwind the C stack and remove the current procedure frame from the stack. Then fail.
plus	$expr_1 + expr_2$
pnull	Push a null descriptor.
pop	Pop the top descriptor.
power	$expr_1 \wedge expr_2$
pret	Dereference the descriptor on the top of the stack, if necessary, and copy it to the place where the descriptor for the procedure is. If &trace is nonzero; decrement it and produce a trace message. Unwind the C stack and remove the current procedure frame from the stack.
psusp	Copy the descriptor on the top of the stack to the place where the descriptor for the procedure is, dereferencing it if necessary. Produce a trace message and decrement &trace if it is nonzero. Create a generator frame containing a copy of the portion of the stack that is needed if the procedure call is resumed.
push1	Push a descriptor for the integer 1.
pushn1	Push a descriptor for the integer -1.
quit	Exit from the interpreter.

random	<i>?expr</i>
rasgn	<i>expr<sub>1</sub> &lt;- expr<sub>2</sub></i>
rcv	To be completed
rcvbk	To be completed
real n	Push a descriptor for the real number block at offset n onto the stack. Becomes opcode areal on subsequent executions.
refresh	<i>^ expr</i>
rswap	<i>expr<sub>1</sub> &lt;-&gt; expr<sub>2</sub></i>
sdup	Push a copy of the descriptor on the top of the stack.
sect	<i>expr<sub>1</sub> [expr<sub>2</sub> : expr<sub>3</sub> ]</i>
size	<i>*expr</i>
static n	Push a variable descriptor pointing to static identifier at offset n. Becomes opcode astatic on subsequent executions.
snd	To be completed
sndbk	To be completed
str n, a	Push a descriptor for the string of length n at offset a. Becomes opcode astr on subsequent executions.
subsc	<i>expr<sub>1</sub>[expr<sub>2</sub>]</i>
swap	<i>expr<sub>1</sub> :=: expr<sub>2</sub></i>
tabmat	<i>=expr</i>
toby	<i>expr<sub>1</sub> to expr<sub>2</sub> by expr<sub>3</sub></i>
unions	<i>expr<sub>1</sub> ++ expr<sub>2</sub></i>
unmark	Remove the current expression frame from the stack and unwind the C stack.
value	<i>.expr</i>
var	Pseudo-instruction; declares variables in ucode.

# Appendix C

## Virtual Machine Code

The virtual machine code that is generated for various kinds of Icon expression is listed below. The form of code given is icode, the output of the Icon linker cast in a readable format. The ucode produced by the Icon translator, which serves as input to the Icon linker, is slightly different in some cases, since the linker performs some refinements.

### C.1 Identifiers

As mentioned in Sec. 8.2.2, the four kinds of identifiers are distinguished by where their values are located. All are referred to by indices, which are zero based.

The values of global identifiers are kept in an array that is loaded from the icode file and is at a fixed place in memory during program execution. By convention, the zeroth global identifier contains the procedure descriptor for main. The following instruction pushes a variable pointing to the value of main onto the interpreter stack:

main	global	0
------	--------	---

Static identifiers are essentially global identifiers that are only known on a per-procedure basis. Like global identifiers, the values of static identifiers are in an array that is at a fixed location. Static identifiers are numbered starting at zero and continuing through the program. For example, if count is static identifier 10 the following instruction pushes a variable descriptor pointing to that static identifier onto the stack:

count	static	10
-------	--------	----

The space for the values of arguments and local identifiers is allocated on the stack when the procedure in which they occur is called. If x is argument zero and i is local zero for the current procedure, the following instructions push variable descriptors for them onto the stack:

x	arg	0
---	-----	---

i	local	0
---	-------	---

## C.2 Literals

The virtual machine instruction generated for an integer literal pushes the integer onto the stack as an Icon descriptor. The value of the integer is the argument to the instruction:

100	int	100
-----	-----	-----

The instruction generated for a string literal is similar to that for an integer literal, except that the address of the string and its length are given as arguments. The string itself is in a region of data produced by the linker and is loaded as part of the icode file:

"hello"	str	5,a1
---------	-----	------

The instruction generated for a real or cset literal has an argument that is the address of a data block for the corresponding value. Such blocks are in the data region generated by the linker:

100.2	real	a2
-------	------	----

'aeiou'	cset	a3
---------	------	----

## C.3 Keywords

The instruction generated for most keywords results in a call to a C function that pushes a descriptor for the keyword onto the stack. The argument is an index that identifies the keyword. For example, &date is keyword 4:

&date	keywd	4
-------	-------	---

Some keywords correspond directly to virtual machine instructions. Examples are &null and &fail:

&null	pnull
-------	-------

&fail	efail
-------	-------

## C.4 Operators

The code generated for a unary operator first pushes a null descriptor, then evaluates the code for the argument, and finally executes a virtual machine instruction that is specific to the operator:

*expr	pnull <i>code for expr</i> size
-------	---------------------------------------

The code generated for a binary operator is the same as the code generated for a unary operator, except that there are two arguments:

expr1 + expr2	pnull <i>code for expr1</i> <i>code for expr2</i> plus
---------------	---

An augmented assignment operator uses the virtual machine instruction dup to duplicate the result produced by its first argument:

expr1 += expr2	pnull <i>code for expr1</i> dup <i>code for expr2</i> plus asgn
----------------	--

The difference between the code generated for left- and right-associative operators is illustrated by the following examples:

expr1 + expr2 + expr3	<p>pnull  pnull  <i>code for expr1</i>  <i>code for expr2</i>  plus  <i>code for expr3</i>  plus</p>
-----------------------	--

expr1 := expr2 := expr3	<p>pnull  <i>code for expr1</i>  pnull  <i>code for expr2</i>  <i>code for expr3</i>  asgn  asgn</p>
-------------------------	--

A subscripting expression is simply a binary operator with a distinguished syntax:

expr1 [ expr2 ]	<p>pnull  <i>code for expr1</i>  <i>code for expr2</i>  subsc</p>
-----------------	---

A sectioning expression is a ternary operator:

expr1 [ expr2 : expr3 ]	<p>pnull  <i>code for expr1</i>  <i>code for expr2</i>  <i>code for expr3</i>  sect</p>
-------------------------	---

Sectioning expressions with relative range specifications are simply abbreviations. The virtual machine instructions for them include the instructions for performing the necessary arithmetic:

expr1 [ expr2 +: expr3 ]	<p>null  code for expr1  code for expr2  dup  code for expr3  plus  sect</p>
--------------------------	--

A to-by expression is another ternary operator with a distinguished syntax:

expr1 to expr2 by expr3	<p>null  code for expr1  code for expr2  code for expr3  toby</p>
-------------------------	---

If the by clause is omitted, an instruction that pushes a descriptor for the integer is supplied:

expr1 to expr2	<p>null  code for expr1  code for expr2  push1  toby</p>
----------------	--

The code generated for an explicit list is similar to the code generated for an operator. The instruction that constructs the list has an argument that indicates the number of elements in the list:

[expr1, expr2, expr3]	<p>null  code for expr1  code for expr2  code for expr3  llist</p>
-----------------------	--

## C.5 Calls

The code generated for a call also is similar to the code generated for an operator except that a null descriptor is not pushed (it is provided by the invoke instruction). The argument of invoke is the number of arguments present in the call, not counting the zeroth argument, whose value is the procedure or integer that is applied to the arguments:

expr0(expr1, expr2)	<i>code for expr0</i> <i>code for expr1</i> <i>code for expr2</i> invoke     2
---------------------	---

In a mutual evaluation expression in which the zeroth argument of the "call" is omitted, the default value is -1, for which an instruction is provided:

(expr1, expr2, expr3)	pushn1 <i>code for expr1</i> <i>code for expr2</i> <i>code for expr3</i> invoke     3
-----------------------	---

## C.6 Compound Expressions and Conjunction

The difference between a compound expression and a conjunction expression is illustrated by the following examples. Note that the code generated for conjunction is considerably simpler than that generated for a compound expression, since no separate expression frames are needed:

{expr1; expr2; expr3}	mark     L1 <i>code for expr1</i> unmark L1: mark     L2 <i>code for expr2</i> unmark L2: <i>code for expr3</i>
-----------------------	---

expr1 & expr2 & expr3	<i>code for expr1</i> pop <i>code for expr2</i> pop <i>code for expr3</i>
-----------------------	---

## C.7 Selection Expressions

In the code generated for an if-then-else expression, the control expression is bounded and has an expression frame of its own:

if expr1 then expr2 else expr3	mark      L1 <i>code for expr1</i> unmark <i>code for expr2</i> goto      L2 L1: <i>code for expr3</i> L2:
-----------------------------------	---

If the else clause is omitted, mark0 is used, so that if the control expression fails, this failure is transmitted to the enclosing expression frame:

if expr1 then expr2	mark0 <i>code for expr1</i> unmark <i>code for expr2</i>
---------------------	---

The code generated for a case expression is relatively complicated. As for similar control structures, the control expression is bounded. The result it produces is placed on the top of the stack by the *eret* instruction, which saves the result of evaluating *expr1*, removes the current expression frame, and then push the saved result on the top of the stack. The *ccase* instruction pushes a null descriptor onto the stack and duplicates the descriptor just below the current *efp* on the top of the stack. This has the effect of providing a null descriptor and the first argument for the equivalence comparison operation performed by *eqv*. The second argument of *eqv* is provided by the code for the selector clause. The remainder of the code for a case clause removes the current expression frame marker, in case the comparison succeeds, and evaluates the selected expression:

## C.8 Negation

The not control structure fails if its argument succeeds but produces the null value if its argument fails:

not expr	mark      L1 <i>code for expr</i> unmark efail  L1:  pnull
----------	---

## C.9 Generative Control Structures

If the first argument of an alternation expression produces a result, esusp produces a generator frame for possible resumption and duplicates the surrounding expression frame on the top of the stack. The result of the first argument is then pushed on the top of the stack, so that it looks as if the first argument merely produced a result. The second argument is then bypassed. When the first argument does not produce a result, its expression frame is removed, leaving the second argument to be evaluated:

expr1   expr2	mark      L1 <i>code for expr1</i> esusp goto      L2  L1:  <i>code for expr2</i>  L2:
---------------	---

Since alternation is treated as a binary operation, a succession of alternations produces the following code:

expr1   expr2   expr3	
	mark      L1
	<i>code for expr1</i>
	esusp
	goto      L2
	L1:
	mark      L3
	<i>code for expr2</i>
	esusp
	goto      L2
	L2:
	<i>code for expr3</i>
	L3:

Repeated alternation is complicated by the special treatment of the case in which its argument does not produce a result. If it does not produce a result, the failure is transmitted to the enclosing expression frame, since the failure ipc is 0. However, if it produces a result, the failure ipc is changed by `chfail` so that subsequent failure causes transfer to the beginning of the repeated alternation expression. The `esusp` instruction produces the same effect as that for regular alternation. Note that changing the failure ipc only affects the expression frame marker on the stack. When `mark` is executed again, a new expression frame marker with a failure ipc of 0 is created.

expr	L1:
	mark0
	<i>code for expr</i>
	chfail      L1
	esusp

In the limitation control structure, the normal left-to-right order of evaluation is reversed and the limiting expression is evaluated first. The `limit` instruction checks that the value is an integer and pushes it. It then creates an expression frame marker with a zero failure ipc. Thus, the limit is always one descriptor below the expression marker created by the subsequent `mark` instruction. The `lsusp` instruction is similar to the `esusp` instruction, except that it checks the limit. If the limit is zero, it fails instead of suspending. Otherwise, the limit is decremented:

$expr1 \setminus expr2$	<i>code for expr2</i> limit <i>code for expr1</i> lsusp
-------------------------	--

## C.10 Loops

The code generated for a repeat loop assures that the expression frame is handled uniformly, regardless of the success or failure of the expression:

repeat expr	L1: mark        L1 <i>code for expr</i> unmark goto        L1
-------------	---

A while loop, on the other hand, transmits failure to the enclosing expression frame if its control expression fails. Note that both *expr1* and *expr2* are evaluated in separate expression frames:

while expr1 do expr2	L1: mark0 <i>code for expr1</i> unmark mark <i>code for expr2</i> goto        L1
----------------------	--

If the do clause is omitted, the generated code is similar to that for a repeat loop, except for the argument of mark:

while expr	L1: mark0 <i>code for expr</i> unmark goto        L1
------------	--

An until loop simply reverses the logic of a while loop:

until <i>expr1</i> do <i>expr2</i>	L1: mark        L2 <i>code for expr1</i> unmark efail  L2: mark        L1 <i>code for expr2</i> unmark goto        L1
------------------------------------	---

The every-do control structure differs from the while-do control structure in that when its control expression produces a result, its expression frame is not removed. Instead, the result is discarded by pop, and the do clause is evaluated in its own expression frame. The efail instruction forces the resumption of a suspended generator that may have been produced by an esusp instruction in the code for *expr1*:

every <i>expr1</i> do <i>expr2</i>	mark0 <i>code for expr1</i> pop mark0 <i>code for expr2</i> unmark efail
------------------------------------	--

Breaks from loops normally occur in the context of other expressions. In the following example, the break expression removes the expression frame corresponding to the repeat control structure, evaluates its argument expression, and then transfers to a point beyond the end of the loop:

<pre>repeat   expr1   break expr2</pre>	<pre> L1:     mark    L1     mark    L3     code for expr1     esusp     goto    L4 L3:     unmark     code for expr2     goto    L2 L4:     unmark     goto    L1 L2:</pre>
---	--

Like break, next normally occurs in the context of other expressions. In the following example, next transfers control from a selection expression to the beginning of the loop:

<pre>while expr1 do   if expr2 then next   else expr3</pre>	<pre> L1:     mark0     code for expr1     unmark     mark    L1     mark    L4     code for expr2     unmark     goto    L2 L4:     code for expr3 L2:     unmark     goto    L1</pre>
---	---

## C.11 String Scanning

String scanning is a control structure, rather than an operator, since the values of `&subject` and `&pos` must be saved and new values established before the second argument is evaluated. This is accomplished by `bscan`. The instruction `bscan` saves the current values of `&subject` and `&pos` and establishes their new values before `expr2` is evaluated. `escan` restores their values prior to the execution of `bscan`:

expr1 ? expr2	<i>code for expr1</i> bscan <i>code for expr2</i> escan
---------------	--

Augmented string scanning is similar to other augmented operations, but it differs in that the string scanning operation does not push a null value on the stack. The instruction sdup therefore is slightly different from dup, which is used in other augmented assignment operations:

expr1 ?:= expr2	pnull <i>code for expr1</i> sdup bscan <i>code for expr2</i> escan asgn
-----------------	---

## C.12 Procedure Returns

The code generated for a return expression consists of the pret instruction. However, it allows for failure of the argument of return, which is equivalent to fail:

return expr	mark      L1 <i>code for expr</i> pret L1: pfail
-------------	--

fail	pfail
------	-------

The code generated for the suspend expression is analogous to the code generated for alternation, except that the result is returned from the current procedure. The efail instruction causes subsequent results to be produced if the call is resumed:

suspend <i>expr</i>	mark0 <i>code for expr</i> psusp efail
---------------------	---

### C.13 Co-Expression Creation

The first instruction in the code generated for a create expression is a transfer around the code that is executed when the resulting co-expression is activated. The create instruction constructs a descriptor that points to the co-expression whose code is at the label given in its argument and pushes this descriptor on the stack. When the co-expression is activated the first time, evaluation starts at the label stored in the co-expression. The result that is on the top of the stack is popped, since transmission of a result to the first activation of a co-expression is meaningless. If *expr* produces a result, coret returns that result to the activating co-expression. If *expr* fails, cofail signals failure to the activating co-expression:

create <i>expr</i>	goto       L3 L1: pop mark       L2 <i>code for expr</i> coret efail L2: cofail goto       L2 L3: create      L1
--------------------	---

# Appendix D

## Adding Functions and Data Types

Icon is designed so that new functions and data types can be added with comparative ease. This appendix provides some guidelines for modifying the Icon run-time system and lists useful macro definitions and support routines. It is designed to be read in conjunction with the source code for the implementation. The material included here only touches on the possibilities. There is no substitute for actually implementing new features and spending time studying the more intricate parts of the Icon system.

This appendix provides an action summary of how to extend the language implementation. For non-trivial additions, the reader should consult Appendix G which contains a detailed description of the RTL language in which the run-time system is written.

### D.1 File Organization

The Icon system is organized in a hierarchy. Under UNIX, the root of the Icon hierarchy is called `icon.git/trunk` (the Unicon root directory is called `unicon`) and may be located anywhere. Neither Icon nor Unicon depends on the name of the root directory and, for other operating systems, it may be named differently.

The *root* directory has several subdirectories that contain source code, test programs, documents, and so forth. The source code is in *root/src*. The subdirectories of *src* are shown below.

The subdirectory *h* holds header files that are included by files in the other subdirectories. The file *h/rt.h* contains most of the definitions and declarations used in the run-time system.

The rest of the code related to the run-time system is in the subdirectory *runtime*. Source file extensions in this directory are *.r* and *.ri* for “run-time” and “run-time include” files which are processed by *rtt*. First letters of files in this subdirectory indicate the nature of their contents. Files that begin with the letter *f* contain code for functions, while files that begin with *o* contain code for operators. Code related directly to the interpretive process is in files that begin with the letter *i*. “Library” routines for operations such as list construction that correspond to virtual machine

instructions are in files that begin with the letter l. Finally, files that begin with the letter r hold run-time support routines.

Within each category, routines are grouped by functionality. For example, string construction functions such as map are in fstr.r, while storage allocation and garbage collection routines are in rmemmgt.r.

A simplified file structure is shown below. The emphasis is on directories that contain source or documentation. Directories that are common to both Icon and Unicon are in black; Icon specific directories are shown in grey; Unicon specific directories are shown in blue. In some cases there is additional sub-structure not shown here.

## D.2 Adding Functions

There are several conventions and rules of protocol that must be followed in writing a new function. The situations that arise most frequently are covered in the following sections. The existing functions in f files in runtime provide many examples to supplement the information given here.

## D.2.1 Function Declarations

A function begins with the RTL header `function{...} name(args)`, where `name` is the name of the function as it is called in a source-language program. For example,

```
function{1} map(s1,s2,s3)
```

appears at the beginning of the function `map`. This header declares the procedure block for the function and includes information about its number of results (in curly brackets) and the number and names of its parameters. See Appendix G.

A `Z` is prepended to the name given to avoid a collision with the names of other C routines in the run-time system. Thus, the C function that implements `map` is named `Zmap`. Although the Icon function `map` has three arguments, the corresponding C function has only one: `r_args`, which is a pointer to an array of descriptors on the interpreter stack. For example, function `{1} map(s1,s2,s3)` generates

```
int Zmap(r_args)
dptr r_args;
```

A new function must also be listed via a one-line macro in `src/h/fdefs.h`. For a fixed number of arguments the macro is `FncDef(name,nargs)` and for a variable number of arguments the macro is `FncDefV(name)`.

## D.2.2 Returning from a Function

A function returns control to the interpreter by use of one of three reserved words `return`, `suspend`, or `fail`, depending on whether the function returns, suspends, or fails, respectively. `return` and `fail` return codes that the interpreter uses to differentiate between the two situations. `suspend` returns control to the interpreter by calling it recursively, as described in Sec. 9.3.

The use of `return` is illustrated by the following trivial function that simply returns its argument:

```
function{1} idem(x)
abstract { return type(x) }
body {
    return x;
}
end
```

For example,

```
write(idem("hello"))
```

writes `hello`.

The use of `suspend` and `fail` is illustrated by the following function, which generates its first and second arguments in succession:

```

function{2} gen2(x,y)
abstract { return type(x) ++ type(y) }
body {
    suspend x;
    suspend y;
    fail;
}

```

For example,  
 every write(gen2("hello", "there"))  
 writes

```

hello
there

```

As illustrated previously, fail is used when there is not another result to produce. It is safe to assume that arguments are intact when the function is resumed to produce another result.

Most functions have a fixed number of arguments. A number of functions such as write, writes, and stop in the standard Icon repertoire can be called with an arbitrary number of arguments. For a function that can be called with an arbitrary number of arguments, the final RTL argument is given a square brackets enclosing a number of arguments, as in function1 name(x[nargs]). When this format is used, the function is called with two arguments: the number of arguments in the call and a pointer to the corresponding array of descriptors. For example, function1 write(x[nargs]) generates

```

Zwrite(r_nargs, r_args)
int r_nargs;
dptr r_args;

```

Within such a function, the arguments are referenced using array syntax. For example, a function that takes an arbitrary number of arguments and suspends with them as values in succession is

```

function{*} gen(x[n])
abstract { return type(x[]) } /* probably doesn't work */
body {
    register int i;
    for (i = 0; i < n; i++) {
        suspend x[i];
    }
    fail;
}

```

For example,

```
every write(gen("hello","there","!"))
writes
```

```
hello
there
!
```

Note the use of fail at the end of the function; the omission of fail would be an error, since returning by flowing off the end of the function would not provide the return code that the interpreter expects.

### D.2.3 Type Checking and Conversion

Some functions need to perform different operations, depending on the types of their arguments. An example is type(x):

```
function{1} type(x)
abstract { return string }
body {
  type_case x of {
    string: inline { return C_string "string"; }
    null: inline { return C_string "null"; }
    integer: inline { return C_string "integer"; }
    real: inline { return C_string "real"; }
    cset: inline { return C_string "cset"; }
    :
  }
}
```

Icon values are stored in descriptors, wherein the d-word serves to differentiate between types. Strings require a separate test prior to examining the d-word's type code, but this is abstracted by the RTL type\_case construct.

For most functions, arguments must be of a specific type. As described in Sec. 12.1, type conversion routines are used for this purpose. For example, the function pos(i) requires that i be an integer. It begins as follows:

```

function{0,1} pos(i)
  if !cnv:C_integer(i) then runerr(101, i);
  abstract { return integer }
body {
  :

```

The RTL syntax for type conversion and defaulting turns around and calls underlying C functions such as `cnv_int()` which are defined in `src/runtime/cnv.r`. If the conversion is successful, the resulting integer is assigned to `i`. As indicated by this example, it is the responsibility of a function to terminate execution by calling `runerr` if a required conversion cannot be made.

Two string conversion functions are available. `cnv_str()` allocates space for the converted string from the heap, while `cnv_tstr()` requires a buffer, which is supplied by the routine that calls it. See Sec. 4.4.4. This buffer must be large enough to hold the longest string that can be produced by the conversion of any value. This size is given by the defined constant `MaxCvtLen`. For example, the function to reverse a string begins as follows:

```

function{0,1} match(s1,s2,i,j)
  :
  if !cnv:tmp_string(s1) then runerr(103,s1)

```

for which the generated C code looks like

```

int Zmatch(dptr r_args)
  :
  char r_sbuf[1][MaxCvtLen];
  :
  if (!cnv_tstr(r_sbuf[0], &(r_args[1]), &(r_args[1]))) {
  { err_msg(103, &(r_args[1])); } }

```

The buffer is used only if a nonstring value is converted to a string. In this case, `r_args[1]` is changed to a qualifier whose v-word points to the converted string in `r_sbuf[0]`. This string does not necessarily begin at the beginning of `r_sbuf[0]`. In any event, after a successful call to `cnv_tstr`, the argument is an appropriate qualifier, regardless of whether a conversion actually was performed.

## D.2.4 Constructing New Descriptors

Some functions need to construct new descriptors to return. RTL is aware that functions return descriptors and given type information, its return statement will construct a descriptor for you. As given in the function `type()` previously, for example, to return a qualifier for the string "integer", the following code suffices:

```
return C_string "integer";
```

Sometimes it is convenient to explicitly construct a descriptor by assignment to its d- and v-words. Various macros are provided to simplify these assignments. `StrLen()` and `StrLoc()` can be used to construct a qualifier.

```
StrLen(result) = 7;
StrLoc(result) = "integer";
return result;
```

In these last two examples, the returned qualifier points to a statically allocated C string.

There also are macros and support routines for constructing certain kinds of descriptors. For example, the macro

```
MakeStr("integer", 7, &result);
```

accomplishes the same as the two assignments to `StrLoc()` and `StrLen()` in the preceding example, and

```
MakeInt(i, &result);
```

constructs an integer descriptor containing the integer `i` in the descriptor `result`.

## D.2.5 Default Values

Many functions specify default values for null-valued arguments. There are RTL constructs for providing default values. For example,

```
def:tmp_string(arg, q)
```

changes `arg` to the string given by the qualifier `q` in case `arg` is null-valued. If `arg` is not null-valued, however, its value is converted to a string, if possible, by `def_tstr`. If this is not possible, the function should terminate execution with an error message.

## D.2.6 Storage Allocation

Functions that construct new data objects often need to allocate storage. Allocation is done in the allocated string region or the allocated block region, depending on the nature of the object. Support routines are provided to perform the actual allocation.

As mentioned in Sec. 11.4, under certain circumstances such as to guarantee that multiple string allocations are adjacent during a concatenation, predictive need requests may be required before storage is actually allocated. The function `reserve(r, i)` requests `i` bytes of contiguous storage in region `r`.

Such a request generally should be made as soon as an upper bound on the amount of storage needed is known. It is not necessary to know the exact amount, but the amount requested must be

at least as large as the amount that actually will be allocated. For example, the function `reads(f, i)` requests `i` bytes of string storage, although the string actually read may be shorter.

**String Allocation.** The function `alcstr(s, i)` copies `i` bytes starting at `s` into the allocated string region and returns a pointer to the beginning of the copy. For example, a function `double(s)` that produces the concatenation of `s` with itself is written as follows:

```
function1 double(s)
abstract { return string }
if !cnv:str(s) then runerr(103, s)
body {
    register int slen = StrLen(s);
    reserve(Strings, 2 * slen);
    StrLen(result) = 2 * slen;
    StrLoc(result) = alcstr(StrLoc(s), slen);
    alcstr(StrLoc(s), slen);
    return result;
}
```

If the first argument of `alcstr` is `NULL`, instead of being a pointer to a string, the space is allocated and a pointer to the beginning of it is returned, but nothing is copied into the space. This allows a function to construct a string directly in the allocated string region.

If a string to be returned is in a buffer as a result of conversion from another type, care must be taken to copy this string into the allocated string region — otherwise the string in the buffer will be overwritten on subsequent calls. Copying such strings is illustrated by the function `string(x)` given in Sec. 12.1.

**Block Allocation.** The block allocation code all lives in `src/runtime/ralc.r`. Macros `AlcFixBlk(var, structname, typecode)` and `AlcVarBlk(var, structname, typecode, numdescriptors)` allocate fixed and variable-sized blocks, respectively. They are generally used internally by run-time support routines for allocating each kind of blocks. Such support routines generally initialize block as well. For example, `alccset()` allocates a block for a `cset`, fills in the title and size words, and zeroes the bits for the `cset`:

```
struct b_cset *alccset()
{
    register struct b_cset *blk;
    register i;
    :
    AlcFixBlk(blk, b_cset, T_Cset);
    blk->size = -1; /* flag size as not yet computed */
}
```

```

/*
 * Zero the bit array.
 */
for (i = 0; i < CsetSize; i++)
    blk->bits[i] = 0; return blk;
}

```

See Sec. D.5.5 for a complete list of block-allocation functions.

## D.2.7 D.2.7 Storage Management Considerations

In addition to assuring that predictive need requests are made before storage is allocated, it is essential to assure that all descriptors contain valid data at any time a garbage collection may occur, that all descriptors are accessible to the garbage collector, and that all pointers to allocated data are in the v-words of descriptors.

Normally, all the descriptors that a function uses are on the interpreter stack. Such descriptors are processed by the garbage collector. Occasionally, additional descriptors are needed for intermediate computations. If such descriptors contain pointers in their v-words, and if a function body allocates storage or suspends control to code that may allocate storage (potentially triggering a garbage collection), it is *not* correct to declare local descriptors, as in

```

function{1} mesh(x,y)
:
body {
    struct descrip d1, d2;
    :
    subsequent code that may allocate memory, or suspend

```

The problem with this approach is that d1 and d2 are on the C stack and the garbage collector has no way of knowing about them.

RTL syntax provides the *tended* keyword for this situation:

```

function{1} mesh(x,y)
body {
    tended struct descrip d1, d2;
    :
    subsequent code that may allocate memory, or suspend

```

Garbage collection can occur only during an allocation or predictive need request. However, this can occur between the time a function suspends and the time it is resumed to produce another result. Consequently, if a pointer is kept in a C variable in a loop that is producing results by suspending, the pointer may be invalid when the function is resumed. Instead, the pointer should be kept in the v-word of a descriptor that is tended, i.e. accessible to the garbage collector.

### D.2.8 Error Termination

An Icon program may terminate abnormally for two reasons: as the result of a source-language programming error (such as an invalid type in a function call), or as a result of an error detected in the Icon system itself (such as a descriptor that should have been dereferenced but was not).

In case a source-language error is detected, execution is terminated by a call of the form  
`runerr(i, &d);`

where *i* is an error message number and *d* is the descriptor for the offending value. If there is no specific offending value, the second argument is 0.

The array of error message numbers and corresponding messages is contained in `runtime/data.r`. If there is no appropriate existing error message, a new one can be added, following the guidelines given in Appendix G of Griswold and Griswold 1990.

In theory, there should be no errors in the Icon system itself, but no large, complex software system is totally free of errors. Some situations are recognizable as being potential sources of problems in case data does not have the expected values. In such situations, especially during program development, it is advisable to insert calls of the function `syserr`, which terminates execution, indicating that an error was detected in the Icon system, and prints its argument as an indication of the nature of the error. It is traditional to use calls of the form

`syserr("mesh: can't happen");`

so that when, in fact, the “impossible” does happen, there is a reminder of human frailty. More informative messages are desirable, of course.

### D.2.9 Header Files

For RTL .r files, the necessary header files normally will be included automatically. Several of them are processed by `rtt` itself; its input automatically includes `src/h/grttin.h` which includes several of the header files, special macros, and a bunch of *ersatz* typedef's to fool `rtt` into parsing successfully without the system includes.

The rest of the includes actually happen during the C compile on `rtt`'s output since system includes may use compiler-specific extensions that `rtt` would not know about. `rtt` writes an include to `src/h/rt.h` to its output files to be processed by the C preprocessor.

The header file `rt.h` includes the full suite of header files:

<code>../h/define.h</code>	platform specific definitions
<code>../h/arch.h</code>	(Icon only) automatically generated word size definitions
<code>../h/config.h</code>	general configuration information
<code>../h/sys.h</code>	system include files (stdio.h etc.)
<code>../h/typedefs.h</code>	type definitions for the run-time system
<code>../h/cstructs.h</code>	structure definitions and constants for the functions in the src/common directory
<code>../h/mproto.h</code>	(Icon only) prototypes for functions common to several modules
<code>../h/proto.h</code>	<a href="#">(Unicon only) prototypes for library functions</a>
<code>../h/cpuconf.h</code>	definitions that depend on the computer word size
<code>../h/monitor.h</code>	<a href="#">(Unicon only) event code definitions</a>
<code>../h/rmacros.h</code>	macros and manifest constants
<code>../h/rstructs.h</code>	runtime data structures
<code>../h/graphics.h</code>	graphics facilities (if configured)
<code>../h/audio.h</code>	audio facilities (Unicon only; if configured)
<code>../h/posix.h</code>	posix facilities (Unicon only)
<code>../h/messaging.h</code>	messaging facilities (Unicon only)
<code>../h/rexterns.h</code>	extern declarations for global variables
<code>../h/rproto.h</code>	runtime system function prototypes

All of these files contain appropriate information for the local installation, and no changes in them should be needed.

### D.2.10 Installing a New Function

Both the linker and the run-time system must know the names of all functions. This information is provided in the header file `h/fdefs.h`.

In order to add a function, a line of the form

```
FncDef(name)
```

must be inserted in `h/fdefs.h` in proper alphabetical order.

Once this insertion is made, the Icon system must be recompiled to take into account the code for the new function. The steps involved in recompilation vary from system to system. Information concerning recompilation is available in system-specific installation documents.

## D.3 Adding Data Types

Adding a new data type is comparatively simple, although there are several places where changes need to be made. Failure to make all the required changes can produce mysterious bugs.

### D.3.1 Type Codes

At present, type codes range from 0 to 25 ([31 for Unicon](#)). Every type must have a distinct type code and corresponding definitions. These additions are made in `h/rmacros.h`. First, a `T_` definition is needed. For example, if a Boolean type is added, a definition such as

```
#define T_Boolean 26
```

is needed. The value of `MaxType`, which immediately follows the type code definitions, must be increased to 26 accordingly. Failure to set `MaxType` to the maximum type code may result in program malfunction during garbage collection. See Sec. 11.3.2.

Next a `D_` definition is needed for the d-word of the new type. For a Boolean type, this definition might be

```
#define D_Boolean (T_Boolean | F_Nqual)
```

All nonstring types have the `F_Nqual` flag and their `T_` type code. Types whose v-words contain pointers also have the `F_Ptr` flag.

### D.3.2 Structures

A value of a Boolean type such as the one suggested previously can be stored in the d-word of its descriptor. However, most types contain pointers to blocks in their v-words. In this case, a declaration of a structure corresponding to the block must be added to `h/rstructs.h`. For example, a new rational number data type, with the type code `T_Rational`, might be represented by a block containing two descriptors, one for the numerator and one for the denominator. An appropriate structure declaration for such a block is

```
struct b_rational {
    int title;
    struct descrip numerator;
    struct descrip denominator;
};
```

Since rational blocks are fixed in size, no size field is needed. However, a vector type with code `T_Vector` in which different vectors have different lengths needs a size field. The declaration for such a block might be

```
struct b_vector {
    int title;
    int blksize;
    struct descrip velems[1];
};
```

As mentioned in Sec. 4.4.2, the size of one for the array of descriptors is needed to avoid problems with C compilers. In practice, this structure conceptually overlays the allocated block region, and the number of elements varies from block to block.

Any new structure declaration for a block must be added to the declaration union block in `h/rstructs.h`. The order of the fields in a new structure must follow the rules (discussed next) imposed by the garbage collector.

### D.3.3 D.3.3 Information Needed for Storage Management

In Icon version 8 and later, allocated data may be referred to in two ways: either (as before) in the `v`-word of a descriptor, or in one of the pointers in a structure. All pointers to allocated data must be contained either in the `v`-words of descriptors or in pointers, since this is the only way the garbage collector can locate them. Furthermore, all non-descriptor data (including pointers) must precede any descriptors in a block. The amount of non-descriptor data, and hence the location of the first descriptor in a block, must be the same for all blocks of a given type. Pointers add new constraints: If any pointers are present, they must be in one contiguous group and must precede the first descriptor in the block although they need not be placed immediately before the descriptors. If any block has a variable number of pointers they must be placed at the end of the block (and there can be no descriptors in the block).

As described in Sec. 11.3.2, the garbage collector uses the array `bsizes` to determine the size of a block and the array `firstd` to determine the offset of the first descriptor in the block. These arrays are in `rmemmgt.r`. When a new data type is added, appropriate entries must be made in these arrays. Failure to do so may result in serious bugs that occur only in programs that perform garbage collection, and the symptoms may be mysterious.

There is an entry in `bsizes` for each type code. If the type has no block, the entry is `-1`. If the type has a block of constant size, the entry is the size of the block. Otherwise, the entry is `0`, indicating that the size is in the second word of the block. Thus, the entry for `T_Boolean` would be `-1`, the entry for `T_Rational` would be `sizeof(struct b_rational)`, and the size for `T_Vector` would be `0`.

There is a corresponding entry in `firstd` for each type code that gives the offset of the first descriptor in its corresponding block. If there is no block, the entry is `-1`. If the block contains no descriptors, the entry is `0`. For example, the entry for `T_Boolean` would be `-1`, the entry for `T_Rational` would be `WordSize`, and the entry for `T_Vector` would be `2*WordSize`, where `WordSize` is a defined constant that is the number of bytes in a word.

Two further arrays are used to determine the placement of pointers. `firstp` is analogous to `firstd`: there is one entry per type. If there is no block, the entry is `-1`. If the type has no pointers the value is `0`, otherwise it is the offset of the first pointer in the block. It is possible to infer the number of descriptors from the position of the first and the size of the block, but this inference is not always possible for pointers so an array `ptrno` is used to indicate how many pointers there are for each type.

If there are no pointers, the value is -1. A value of 0 means that the pointers occupy the rest of the block (and the block has no descriptors). Otherwise the entry contains the number of pointers in the block. As with `firstd` and `bsizes`, a failure to initialize `firstp` and `ptrno` correctly may result in serious (and mysterious) bugs.

A fifth array, `blknames`, provides string names for all block types. These names are only used for debugging, and an entry should be made in `blknames` for each new data type.

### D.3.4 Changes to Existing Code

In addition to any functions that may be needed for operating on values of a new data type, there are several functions and operators that apply to all data types and which may, therefore, need to be changed for any new data type.

These are

<code>*x</code>	size of <code>x</code> (in <code>runtime/omisc.r</code> )
<code>copy(x)</code>	copy of <code>x</code> (in <code>runtime/fmisc.r</code> )
<code>image(x)</code>	string image of <code>x</code> (in <code>runtime/fmisc.r</code> )
<code>type(x)</code>	string name of type of <code>x</code> (in <code>runtime/fmisc.r</code> )

There is not a concept of size for all data types. For example, a Boolean value presumably does not have a size, but the size of a vector presumably is the number of elements it contains. The size of a rational number is problematical. Modifications to `*x` are easy; see Sec. 4.4.4.

There must be some provision for copying any value. For structures, such as vectors, physical copies should be made so that they are treated consonantly with other Icon structures. For other data types, the “copy” consists of simply returning the value and not making a physically distinct copy. This should be done for data types, such as Boolean, for which there are only descriptors and no associated blocks. Whether or not a copy of a block for a rational value should be made is a more difficult decision and depends on how such values are treated conceptually, at the source-language level. It is, of course, easiest not to make a physical copy.

Some image must be provided for every value. This image should contain enough information to distinguish values of different types and, where possible, to provide some useful additional information about the specific value. The amount of detail that it is practical to provide in the image of a value is limited by the fact that the image is a string that must be placed in the allocated string region.

The type must be provided for all values and should consist of a simple string name. For example, if `x` is a Boolean value, `type(x)` should produce “boolean”. The coding for `type` is trivial; see Sec. D.2.3.

There also are several run-time support routines that must be modified for any new type:

<code>outimage</code>	image for tracing (in <code>runtime/rmisc.r</code> )
<code>order</code>	order for sorting (in <code>runtime/rcomp.r</code> )
<code>anycmp</code>	comparison for sorting (in <code>runtime/rcomp.r</code> )
<code>equiv</code>	equivalence comparison (in <code>runtime/rcomp.r</code> )

The image produced for tracing purposes is similar to that produced by `image` and must be provided for all data types. However, `outimage` produces output and is not restricted to constructing a string in allocated storage. It therefore can be more elaborate and informative.

There must be some concept of sorting order for every Icon value. There are two aspects to sorting: the relative order of different data types and the ordering among values of the same type. The routine `order` produces an integer that corresponds to the order of the type. If the order of a type is important with respect to other types, this matter must be given some consideration. For example, a rational number probably belongs among the numeric types, which, in Icon, sort before structure types. On the other hand, it probably is not important whether vectors come before or after lists.

The routine `anycmp` compares two values; if they have the same order, as defined previously, `anycmp` determines which is the “smaller.” For example, Boolean “false” might (or might not) come before “true,” but some ordering between the two should be provided. On the other hand, order among vectors probably is not important (or well-defined), and they can be lumped with the other structures in `anycmp`, for which ordering is arbitrary. Sometimes ordering can be quite complicated; a correct ordering of rational numbers is nontrivial.

The routine `equiv` is used in situations, such as table subscripting and case expressions, to determine whether two values are equivalent in the Icon sense. Generally speaking, two structure values are considered to be equivalent if and only if they are identical. This comparison is included in `equiv` in a general way. For example, `equiv` need not be modified for vectors. Similarly, for data types that have no corresponding blocks, descriptor comparison suffices; `equiv` need not be modified for Boolean values either. However, determining the equivalence of numeric values, such as rational numbers, requires some thought.

Although not strictly part of the language proper, there are several routines in the Icon Programming Library and the Unicon class libraries that operate on all types. The addition of new type may require that some of these be modified. A good start to locating code that potentially requires modification is to search for expressions of the form

```
case ... type( ...) ... of
```

## D.4 Defined Constants and Macros

Defined constants and macros are used heavily in Icon to parameterize its code for different operating systems and computer architectures and to provide simple, high-level constructions for commonly occurring code sequences that otherwise would be complex and obscure.

These defined constants and macros should be used consistently when making additions to Icon instead of using *ad hoc* constructions. This improves portability, readability, and consistency.

Learning the meanings and appropriate use of the existing defined constants and macro definitions requires investment of time and energy. Once learned, however, coding is faster, simpler, and less prone to error.

### D.4.1 Defined Constants

The following defined constants are used frequently in the run-time system. This list is by no means exhaustive; for specialized constants, see existing functions.

CsetSize	number of words needed for 256 bits
LogHuge	one plus the maximum base-10 exponent of a C double
LogIntSize	base-2 logarithm of number of bits in a C int
MaxCvtLen	length of the longest possible string obtained by conversion
MaxLong	largest C long
MaxShort	largest C short
MaxStrLen	longest possible string
MinListSlots	minimum number of slots in a list-element block
MinLong	smallest C long
MinShort	smallest C short
WordSize	number of bytes in a word

### D.4.2 Macros

The following macros are used frequently in the run-time system. See `h/rmacros.h` for most of the definitions and the files included by `h/rt.h` for the others; see existing routines for examples of usages.

Arg(n)	nth argument to function
ArgType(n)	d-word of nth argument to function
ArgVal(n)	integer value of v-word of nth argument to function
BlkLoc(d)	pointer to block from v-word of d
BlkSize(cp)	size of block pointed to by cp
BlkType(cp)	type code of block pointed to by cp
ChkNull(d)	true if d is a null-valued descriptor
CsetOff(b)	offset in a word of cset bit b
CsetPtr(b, c)	address of word c containing cset bit b
DeRef( d)	dereference d

<code>EqlDesc(d1, d2)</code>	true if d1 and d2 are identical descriptors
<code>GetReal(dp, r)</code>	get real number into r from descriptor pointed to by dp
<code>IntVal(d)</code>	integer value of v-word of d
<code>Max(i, j)</code>	maximum of i and j
<code>Min(i, j)</code>	minimum of i and j
<code>Mkint(i, dp)</code>	make integer from i in descriptor pointed to by dp
<code>Offset(d)</code>	offset from d-word of variable descriptor d
<code>Pointer(d)</code>	true if v-word of d is a pointer
<code>Qual(d)</code>	true if d is a qualifier
<code>Setb(b, c)</code>	set bit b in cset c
<code>SlotNum(i, j)</code>	Slot for hash number i given j total slots
<code>StrLen(q)</code>	length of string referenced by q
<code>StrLoc(q)</code>	location of string referenced by q
<code>Testb(b, c)</code>	true if bit b in cset c is one
<code>Tvar(d)</code>	true if d is a trapped variable
<code>TvarLoc(d)</code>	pointer to trapped variable from v-word of d
<code>Type(d)</code>	type code in d-word of d
<code>Var(d)</code>	true if d is a variable descriptor
<code>VarLoc(d)</code>	pointer to value descriptor from v-word of d
<code>Vsizeof(x)</code>	size of structure x less variable array at end
<code>Vwsizeof(x)</code>	size of structure x in words less variable array at end
<code>Wsizeof(x)</code>	size of structure x in words

## D.5 Support Routines

There are many support routines for performing tasks that occur frequently in the Icon run-time system. Most of these routines are in files in runtime that begin with the letter r. The uses of many of these support routines have been illustrated earlier; what follows is a catalog for reference.

### D.5.1 Comparison

The following routines in runtime/rcomp.r perform comparisons:

<code>anycmp(dp1, dp2)</code>	Compare the descriptors pointed to by dp1 and dp2 as Icon values in sorting order, returning a value greater than 0, 0, or less than 0 depending on whether the descriptor pointed to by dp1 is respectively greater than, equal to, or less than the descriptor pointed to by dp2.
-------------------------------	---

<code>equiv(dp1, dp2)</code>	Test for equivalence of descriptors pointed to by <code>dp1</code> and <code>dp2</code> , returning 1 if equivalent and 0 otherwise
<code>lexcmp(dp1, dp2)</code>	Compare string qualifiers pointed to by <code>dp1</code> and <code>dp2</code> returning a value greater than 0, 0 or less than 0 depending on whether the string referenced by <code>dp1</code> is respectively greater than, equal to or less than the string referenced by <code>dp2</code>
<code>numcmp(dp1, dp2, dp3)</code>	Compare the descriptors pointed to by <code>dp1</code> and <code>dp2</code> as numbers, putting the converted value of the number referenced by <code>dp2</code> in the descriptor pointed to by <code>dp3</code> and returning 0, 0 or less than 0 depending on whether the number referenced by <code>dp1</code> is respectively greater than, equal to or less than the number referenced by <code>dp2</code>

### D.5.2 Type Conversion

The following routines in `src/runtime/cnv.r` perform type conversions:

<code>cnv_cset(s,d)</code>	Convert the descriptor pointed to by <code>s</code> to a cset and point <code>d</code> to it. Return 1 if the conversion can be performed (or is not needed) and 0 otherwise.
<code>cnv_int(s,d)</code>	Convert the descriptor pointed to by <code>s</code> to an integer and store the value in the location pointed to by <code>d</code> , returning 1 if the conversion can be performed, but 0 otherwise.
<code>ston(dp,union numeric *result)</code>	Convert the string descriptor pointed to by <code>dp</code> to a numeric value and store the value in the location pointed to by <code>result</code> , returning the type if the conversion can be performed, but <code>CvtFail</code> otherwise.
<code>cvpos(i1, i2)</code>	Convert <code>i1</code> to a positive value with respect to the length <code>i2</code> , returning 0 if the conversion is not possible.
<code>cnv_real(sp,dp)</code>	Convert the descriptor pointed to by <code>sp</code> to a real number and store the value in the location pointed to by <code>dp</code> , returning 1 if the conversion can be performed, but 0 otherwise.

<code>cnv_str(sp, dp)</code>	Convert the descriptor pointed to <code>sp</code> to a string, returning 1 if a resulting string was produced, but 0 otherwise.
<code>strprc(dp, i)</code>	Convert the qualifier pointed to by <code>dp</code> to a procedure descriptor if possible, using <code>i</code> as the number of arguments in the case of a string that represents an operator, returning 0 if the conversion cannot be performed.

### D.5.3 Defaults

The following routines in `src/runtime/def.r` produce default values for omitted arguments. They are generally called internally by RTL constructs.

<code>def_cset(sp, df, dp)</code>	If the descriptor pointed to by <code>sp</code> is null, store the cset pointed at by <code>df</code> at the place pointed to by <code>dp</code> and return 1; otherwise convert the descriptor pointed to by <code>dp</code> and return 1 if successful. Return 0 if the conversion cannot be performed.
<code>def_int(sp, df, dp)</code>	If the descriptor pointed to by <code>sp</code> is null, store <code>df</code> at the location pointed to by <code>dp</code> and return 1. Otherwise convert the descriptor pointed to by <code>sp</code> to an integer, store it at the location pointed to by <code>dp</code> , and return 1. Return 0 if the conversion cannot be performed.
<code>def_str(sp, df, dp)</code>	If the descriptor pointed to by <code>sp</code> is null, replace it by the descriptor pointed to by <code>df</code> and return 1. Otherwise convert the descriptor pointed by <code>sp</code> to a string and return 1, but return 0 if the conversion cannot be performed.

### D.5.4 Allocation

The following routines in `runtime/ralc.r` all return pointers to the objects they allocate:

<code>alcbk(i,j)</code>	Allocate a block of <code>i</code> bytes with title <code>j</code> in the allocated block region.
<code>alccoexp()</code>	Allocate a co-expression block.
<code>alccset(i)</code>	Allocate a cset block for a cset, setting its size to <code>i</code> .
<code>alcfile(fp, i, dp)</code>	Allocate a file block. setting its file pointer to <code>fp</code> , its status to <code>i</code> , and its name to the qualifier pointed to by <code>dp</code> .
<code>alclint(i)</code>	Allocate a long-integer block and place <code>i</code> in it.
<code>alclist(i)</code>	Allocate a list-header block and set its size field to <code>i</code> .

<code>alclstb(i1, i2, i3)</code>	Allocate a list element block for <code>i1</code> elements, setting its first field to <code>i2</code> and its <code>nused</code> field to <code>i3</code> .
<code>alcreal(r)</code>	Allocate a real-number block and place <code>r</code> in it.
<code>alcrecd(i, dp)</code>	Allocate a record block with <code>i</code> fields setting its procedure descriptor to the descriptor pointed to by <code>dp</code> .
<code>alcrefresh(ip, i, j)</code>	Allocate a refresh block for a procedure with <code>i</code> arguments, <code>j</code> local identifiers, and entry point <code>ip</code> .
<code>alcselem(dp, i)</code>	Allocate a set-element block, setting its member field to the descriptor pointed to by <code>dp</code> and its hash number field to <code>i</code> .
<code>alcset()</code>	Allocate a set-header block.
<code>alcstr(sbuf, i)</code>	Allocate a string of length <code>i</code> , and copy the string in <code>sbuf</code> into it, provided <code>sbuf</code> is not NULL.
<code>alcsubs(i, j, dp)</code>	Allocate a substring trapped-variable block, setting its length field to <code>i</code> , its offset field to <code>j</code> , and its variable descriptor to the descriptor pointed to by <code>dp</code> .
<code>alctable(dp)</code>	Allocate a table-header block, setting its default descriptor to the descriptor pointed to by <code>dp</code> .
<code>alctelem()</code>	Allocate a table-element block.
<code>alctvtbl(dp1, dp2, i)</code>	Allocate a table-element trapped-variable block, setting its link field to the descriptor pointed to by <code>dp1</code> , its entry field to the descriptor pointed to by <code>dp2</code> , and its hash number field to <code>i</code> .
<code>blkreq(i)</code>	Request <code>i</code> bytes of free space in the allocated block region.
<code>strreq(i)</code>	Request <code>i</code> bytes of space in the allocated string region.

### D.5.5 Operations on Structures

The following routines in `runtime/rstruct.r` perform operations on structures:

<code>addmem(sp, ep, dp)</code>	Add the set-element block pointed to by <code>ep</code> to the set pointed to by <code>sp</code> at the place pointed to by <code>dp</code> .
<code>cplist(dp1, dp2, i, j)</code>	Copy the sublist from <code>i</code> to <code>j</code> of the list referenced by the descriptor pointed to by <code>dp1</code> , and place the result in the descriptor pointed to by <code>dp2</code> .
<code>memb(sp, dp, i, ip)</code>	Set the value pointed to by <code>ip</code> to 1 if the descriptor pointed to by <code>dp</code> is a member of the set pointed to by <code>sp</code> using <code>i</code> as the hash number but to 0 otherwise.

### D.5.6 Input and Output

The following routines in `runtime/rsys.r` perform input and output operations:

<code>getstr(sbuf, i, fp)</code>	Read a line of at most <code>i</code> characters from the file specified by <code>fp</code> , putting the result in <code>sbuf</code> , returning the number of characters read, but returning <code>-1</code> on an end of file.
<code>putstr(fp, sbuf, i)</code>	Write <code>i</code> characters from <code>sbuf</code> on the file specified by <code>fp</code> .

### D.5.7 Error Termination

The RTL construct `runerr()` can appear outside the C code of a body or an inline block, reporting errors in parameters, or it may appear in a block of C code. Authors of new runtime system code generally use `runerr()` and may invent new run-time error codes if needed. Very rarely an internal error may warrant a `syserr()`.

Interestingly, `runerr()` only works in top-level RTL functions and operators, not in underlying C functions. If an underlying runtime system function has a problem that should result in a runtime error, the C function will have to return an error code of some kind to the top-level RTL function or operator that called it, asking it to produce a runtime error.

<code>runerr(i, dp)</code>	Terminate execution with error message <code>i</code> showing the offending value in the descriptor pointed to by <code>dp</code> (optional).
<code>syserr(sbuf)</code>	Terminate execution with system error message <code>sbuf</code> .

### D.5.8 Miscellaneous Operations

The following miscellaneous operations are in `h/rmacros.h` or `runtime/rmisc.r`:

<code>deref(dp)</code>	Dereference the descriptor pointed to by <code>dp</code> .
<code>hash(dp)</code>	Return a hash value for the descriptor pointed to by <code>dp</code> .
<code>outimage(fp, dp, i)</code>	Write an image for the value of the descriptor pointed to by <code>dp</code> on the file to by <code>fp</code> , but not calling recursively if <code>i</code> is nonzero.
<code>qtos(qp, sbuf)</code>	Convert the string represented by the qualifier pointed to by <code>qp</code> to a null-terminated C-style string in <code>sbuf</code> .

### D.5.9 Diagnostics

There are two routines in `runtime/rmemmgt.r` for producing diagnostic output. They are not included in the runtime system unless you build it with `DeBugIconx` defined in your `define.h`.

<code>descr(dp)</code>	Write a diagnostic diagram of the descriptor pointed to by <code>dp</code> to standard error output.
<code>blkdump</code>	Write a diagnostic diagram of the allocated block region to standard error output.

## D.6 Debugging

Debugging a modification to Icon can be difficult unless the overall structure of the Icon system is understood. It is especially important to understand the way Icon's data is organized and how storage management works. If an addition to Icon does not work properly, or if Icon itself no longer functions correctly after a modification, it is generally advisable to *think* about the possible sources of problems, instead of immediately resorting to a debugger.

Print statements are a crude but often effective means of locating the source of an error. When adding diagnostic output use

```
fprintf(stderr, "...", ...);
```

instead of the corresponding `printf`. On some systems it may be useful to follow such calls by `fflush(stderr)` to ensure that the diagnostic output appears as soon as it is produced.

Icon normally traps floating-point exception and illegal addressing (segmentation violations) since these errors can result from source-language programming errors, such as division by real zero and excessive recursion resulting in C stack overflow. For example, Icon normally produces Error 302 ("C stack overflow") in case of a segmentation violation. This method of handling such an error is appropriate if Icon itself is free of bugs, but it interferes with debugging in situations where there are likely to be bugs in new code.

Assigning a value to the environment variable `ICONCORE` turns off the trapping of such errors. In this case most systems produce meaningful diagnostic messages and a core dump in the case of an exception. If `ICONCORE` has a value, a core dump is produced if an Icon program terminates as a result of `runerr` or `syserr`. It is therefore good practice to set `ICONCORE` when making modifications to Icon. For an extended debugging session, it may be convenient to set `dodump` in `runtime/init.r` to 1.

## D.7 Adding new types to the compiler

Editorial Note: This section is derived from Appendix F of the RTL reference document [ipd261.]. The RTL manual is reproduced here as appendix G.

This section describes how to add new types to Icon. It deals with simple types, aggregate types whose values contain other Icon values, and keywords that are variables. These are the kinds of types that are most likely to be added to the language. Executable types such as procedures and co-expressions are beyond the scope of this section, as are types that require special representations and variable types that have special dereferencing semantics.

### D.7.1 The implementation of Icon Types (reprise)

As discussed in part 1 and Appendix A of this compendium, an Icon value is implemented as a two-word *descriptor* containing type information and value information. The first word of a descriptor

is the *d-word*. For the types discussed here, the d-word contains a unique code that identifies the type. The second word of the descriptor is the *v-word*; it contains the actual value or a reference to the value. Actual values that are too large to fit in one word are usually put in the block region. This region is controlled by a storage management system that includes a garbage collector. The garbage collector is driven by information in arrays indexed using the type codes associated with the blocks. The block region contains values for both simple and aggregate types.

There are several other parts of the run-time system besides the garbage collector that need information about Icon types. Some are Icon operations such as the `type()` function, while others are automatically invoked features such as error trace back. These are described in more detail below. Types, of course, typically have operations associated with them that create and use values of the type.

## D.7.2 The Type Specification System

Icon types are used in several places in RTL and new types must be added to this language. These uses include type checking constructs, return/suspend statements, and abstract type computations. In addition, the Icon compiler needs information about types in order to perform type inferencing. These requirements are satisfied with a type specification system.

This system is a simple declarative language for naming types and describing some of their properties. Information from the type specification system is incorporated in `rtd` and in `iconc` when they are built.

All types specified by the system may be used in the RTL `is` and `type_case` constructs. They may also be used in abstract type computations. Aggregate types may be used in a new type expression in an abstract type computation. A type specification may optionally indicate that RTL supports a special form of return/suspend statement that constructs a return value, in the form of a full descriptor, from a C value for the *v-word* of the descriptor.

Type specifications are in the file `common/typespec.txt`. Comments in the file start with `#` and continue to the end of the line.

This file is translated into a C header file by the program `typespec`. This is not part of the normal Icon build process; entries at the end of `common/Makefile` must be uncommented if `typespec.txt` is updated.

A type definition in the specification system has the form:

```
type-def ::= identifier opt-abrv : kind opt-return
```

where *identifier* is the name of the type and *opt-abrv* is an optional abbreviation for the type name. The abbreviation has the form:

```
opt-abrv ::= nil |  
             { identifier }
```

The abbreviation is used in tracing type inferencing and other places where a compact notation is desired. If no abbreviation is given, the full type name is used.

There are three kinds of types: simple, aggregate, and variable. Their syntax and usage are described in separate sections below. *opt-return* indicates optional RTL return/suspend support for the type. The four types of v-words supported by this construct are introduced below as needed. A complete grammar for the specification language is given near the end of this appendix.

### D.7.3 Simple Value Types

Types with a kind clause of *simple* are simple in the sense that values of the type do not have components that contain other Icon values. These types may otherwise have sophisticated semantics.

There are three ways to implement the values of a type: encode them as C integers (these are guaranteed to be at least 32 bits long), implement them as blocks in the block region, or implement them in storage allocated using `malloc()` (in theory values can also be put in the string region, but it is only well suited for Icon strings; descriptors pointing into this region must have a special form — described in A.1.1). The choice of implementation determines the type of C value stored in the v-word of the descriptor representing the Icon value.

The d-word of a descriptor for one of these types contains a fixed code. It consists of a small integer type code along with flags describing characteristics of the descriptor. The necessary changes to `rmacros.h` have been covered earlier in section D.3.1.

Three of the *opt-return* type specification clauses are useful for implementing value types (the fourth is used for variable types; see below). These clauses add return/suspend statements to RTL of the form

```
return  type-name ( expr )
suspend type-name ( expr )
```

*type-name* is the identifier naming the type. It determines the `D_` constant used for the d-word of the operation's result descriptor. *expr* is a C expression whose value is placed in the v-word of the result. The particular *opt-return* clause chosen determines how the C value is stored in the v-word. The clauses are

return <code>C_integer</code>	indicates that the value is cast to a C integer; see the definition of word in <code>h/typedefs.h</code> for the exact C type used.
return <code>block_pointer</code>	indicates that the value is cast to <code>(union block *)</code> ; this is usually used for pointers to blocks in the block region.
return <code>char_pointer</code>	indicates that the value is cast to <code>(char *)</code> . Note, only descriptors of a special form may point into the string region; the storage used with <code>return char_pointer</code> must reside elsewhere.

As an example, the type specification for the `cset` type is

```
cset{c}:  simple
         return block_pointer
```

Suppose a variable `cp` within an Icon operation written in RTL points to a `cset` block. Then the statement

```
return cset(cp);
```

constructs a result descriptor for the `cset` and returns it.

For a type with an associated block, a declaration for the block structure must be added to `h/rstructs.h`. By convention, the structure name is created by prepending `b_` to the type name. The first word of a block must contain its `T_` type code. If different instances of the block may vary in size, the second word of the block must contain this size in bytes. The structure name of the new block must be added to the union block declaration in `h/rstructs.h`. An allocation routine for the block must be added to `runtime/ralc.r`. The macros `AlcFixBlk()` and `AlcVarBlk()` are useful in such routines; see other allocation routines for guidelines.

There are five arrays in `runtime/rmemmgt.r` that must be updated for all types (the details have been covered in section D.3.3).

Storage for the values of a type usually should be allocated in the block region. However, for interfaces to packages written in C, it may be necessary to use storage that is not relocated by garbage collection. While it is possible to place types allocated with `malloc()` under control of garbage collection, this is complicated and beyond the scope of this appendix. See the implementation of co-expressions for an example of how this can be done. Short of modifying the garbage collector to handle a new type's allocated storage, the best practice for any storage allocated with `malloc()` is to provide an Icon function, along the lines of `close()`, that explicitly frees storage associated with a value when the program is finished using it.

The necessary changes to built-in functions and support routines have been covered earlier in section D.3.4.

At the end of this appendix is a check list of files that must be updated when a type is added to Icon.

## D.7.4 Aggregate Types

Aggregate types have values with components that are other Icon values. The aggregate type specification provides more sophisticated RTL abstract type computations for the type. These in turn allow `iconc` to produce code that is better optimized.

For interpreter-only implementations, abstract type computations are not used and are optional in RTL code; the simple type specification may be used in that case. However, the discussion later in this section on block layout and on the storage management arrays still applies.

The *kind* clause of an aggregate type specification establishes and names abstract components for the type. The clause is of the form

*kind* ::= aggregate ( *component*, ... )

*component* ::= *identifier* |  
                  var *identifier* *opt-abrv*

Note, the opt-return clauses discussed in the previous section may be also used with aggregate types.

The aggregate specification can be thought of as establishing a sort of “abstract type record” whose fields, the abstract components, summarize the type information of the actual components of values in the type. Most types are given one abstract component. For example, the set type has the specification

```
set{S}:  aggregate(set_elem)
         return block_pointer
```

where *set\_elem* represents all the elements of a set.

Abstract components can be accessed using dot notation, and the new abstract type computation can be used to establish a new subtype of the type (subtypes only exist internally in the compiler and have no existence at the Icon language level). A subtype can be returned by the operation and has its own component types independent of subtypes created elsewhere. The abstract type computation for Icon set intersection, the **\*\*** operator, uses both dot notation and a new expression. It performs intersection in the abstract type realm. *x* and *y* are the parameters of the operation and may contain different subtypes of the set type:

```
return new set(store[type(x).set_elem] ** store[type(y).set_elem])
```

(Note that the components can be thought of as references to information contained in a *type store* — thus the indexing notation.)

Components that represent Icon variables are preceded by **var** and may be given abbreviations for use in tracing type inferencing. For example, the list type has the specification

```
list{L}:  aggregate(var lst_elem{LE})
         return block_pointer
```

These components may be returned from operations and represent the component as a variable. For example, the abstract type computation for element generation operator when applied to a list is

```
return type(dx).lst_elem
```

where *dx* is the parameter of the operation. When a value rather than a variable is returned, the component must be “dereferenced” by indexing into the store, as in the abstract type computations of *get()*:

```
return store[type(x).lst_elem]
```

Non-variable components must always be dereferenced.

For types, such as tables, that contain Icon values serving different purposes, it may be effective to establish several abstract components.

Aggregate types are implemented using blocks that contain descriptors, and they may be implemented using several kinds of blocks, with some blocks having pointers to others. When there are multiple blocks, there is always a *header* block that uses the *T\_* code of the type. Other blocks are given internal type codes; these codes must be added to *h/rmacros.h* and entries must be made in the storage management arrays.

Any descriptors in a block must be at the end. The type's entry in the *firstd* array is the location of the first descriptor. Any block pointers in the block must be contiguous. The type's entry in the *firstp* array is the location of the first pointer and its entry in the *ptrno* array is the number of pointers.

## D.7.5 Keyword Variable Types

Keyword variable types have a type specification with a *kind* clause of the form

```
kind ::= variable var-type-spec
```

```
var-type-spec ::= initially type |  
                  always type
```

```
type ::= type-name |  
         type ++ type-name
```

```
type-name ::= identifier
```

The compiler must be able to infer the types of values stored in a keyword variable. The *initially* option causes the keyword variable type to be treated as a set of global variables, each initialized to the given type specified by the *type* clause. The *always* option indicates that the keyword always contains values of the given type and the compiler does no actual inference on it. *type* may be the union of several types; this indicates that the type is uncertain and may be any of the ones specified. A special *type-name*, *any\_value*, indicates complete uncertainty.

The clause

```
always any-value
```

is a correct, although entirely imprecise, description of any keyword variable.

This appendix assumes that keyword variables are implemented by global descriptors (though other techniques are possible). The *opt-return* clause of the form

```
return descriptor_pointer
```

is useful for implementing keyword variables. The v-word of a result descriptor from a corresponding return/suspend expression is of type `struct descrip *`.

Some of the same files must be updated for variable types as for value types. Type codes must be added to `h/rmacros.h`. The `D_` code must have the `F_Var` flag set, for example:

```
#define D_Kywdint (T_Kywdint | D_Typecode | F_Ptr | F_Var)
```

The storage management tables and the `outimage()` routine also must be updated.

Other updates are unique to variable types. The global descriptor must be established. `runtime/data.r` contains its declaration. `icon_init()` in `runtime/init.r` initializes the descriptor, and `h/rexterns.h` contains an extern for it. Dereferencing must be updated; it is performed by `deref()` in `runtime/cnv.r`. Assignment must be updated; it is handled by the macro `GeneralAsgn()` in `runtime/oasgn.r`. The `name()` function is updated by changing the support routine `get_name()` in `runtime/rdebug.r`. The `variable()` function is updated by changing the support routine `getvar()` in `runtime/rmisc.r`.

The keyword itself goes in `runtime/keyword.r`. For example, `&random` is of type `kywdint` and is implemented by the descriptor `kywd_ran`; its definition is

```
keyword{1} random
  abstract {
    return kywdint
  }
  inline {
    return kywdint(&kywd_ran);
  }
end
```

For the interpreter, the keyword name must be added to `icont/key_text.c`. These names are in alphabetical order.

If the descriptor may contain a value under control of garbage collection, the support routine `collect()` in `runtime/rmemmgt.r` must be updated. `postqual()` preserves references to the string region; the macro `Qual()` is used to check for such references. `markblock()` preserves references to blocks; the macro `Pointer()` is used to check for such references.

### D.7.6 The Complete Grammar for the Type Specification System

*type-def* ::= *identifier opt-abrv* : *kind opt-return*

*kind* ::= simple |  
aggregate ( *component*, ... ) |  
variable *var-type-spec*

*component* ::= *identifier* |  
var *identifier opt-abrv*

*var-type-spec* ::= initially *type* |  
always *type*

*type* ::= *type-name* |  
*type* ++ *type-name*

*type-name* ::= *identifier*

*opt-abrv* ::= *nil* |  
{ *identifier* }

*opt-return* ::= *nil* |  
return block\_pointer |  
return descriptor\_pointer |  
return char\_pointer |  
return C\_integer

## D.8 A check list for adding types

*(on one page for easy photocopying)*

### All Types

- ☐ common/typespec.txt – add type specification
- ☐ common/Makefile – uncomment entries near the end of the file
- ☐ h/rmacros.h – add *T\_Type* macro
- ☐ h/rmacros.h – add *D\_Type* macro
- ☐ runtime/rmemmgt.r – bsize table
- ☐ runtime/rmemmgt.r – firstd table
- ☐ runtime/rmemmgt.r – firstp table
- ☐ runtime/rmemmgt.r – ptrno table
- ☐ runtime/rmemmgt.r – blkname table
- ☐ runtime/rmisc.r – update outimage()

### All Value Types

- ☐ runtime/fmisc.r – update copy()
- ☐ runtime/fmisc.r – update type()
- ☐ runtime/rcomp.r – update anycmp()
- ☐ runtime/rcomp.r – update order()
- ☐ runtime/rcomp.r – update equiv()
- ☐ runtime/rmisc.r – update getimage()

### Types Implemented In The Block Region

- ☐ h/rstructs.h – add declaration for the block structure
- ☐ h/rstructs.h – update the union block declaration
- ☐ runtime/ralc.r – add an allocation routine

### Types With Sizes

- ☐ runtime/omisc.r – update size operator

### All Keyword Variable Types

- ☐ h/rextens.h – extern for keyword descriptor
- ☐ runtime/cnv.r – update deref()
- ☐ runtime/data.r – declaration for keyword descriptor
- ☐ runtime/init.r – initialize keyword descriptor
- ☐ runtime/keyword.r – add keyword declaration
- ☐ runtime/oasgn.r – update GeneralAsgn() macro

## Solutions to Selected Exercises

2.2 The expression

```
write("hello" | "howdy")
```

just writes hello; there is no context to cause the second argument of the alternation to be produced.

2.3 The expression

```
| (1 to 3) > 10
```

is an evaluation "black hole." The left argument produces 1, 2, 3, 1, 2, 3, 1, 2, 3, ... indefinitely, since the comparison always fails.

3.1 The difference in execution time between interpretation and the execution of compiled code is comparatively small, since most of the time in execution is spent in subroutines that are called in either case.

3.3 The lexical analyzer inserts a semicolon between the lines

```
s1 := s2  
|| s3
```

because an identifier is legal at the end of an expression, and the unary operator for repeated alternation is legal at the beginning of an expression. Thus, the second line consists of two applications of repeated alternation to s3.

4.6 Type checking is a byproduct of conversion. If conversion were not automatic, type checking would be simple, but the conversion routines would still be needed for explicit type conversion. Without implicit type conversion, the programmer would have to perform explicit conversions, as in

```
while sum +:= numeric(read())
```

However, since both read and numeric can fail, a more complicated construction would be advisable:

```

while x := read() do
    sum += numeric(x) | stop("nonnumeric data")

```

This illustrates why the failure of an implicit conversion is an error.

- 4.7 A test is necessary to distinguish between qualifiers and other descriptors, regardless of which has the flags. However, if qualifiers had flags, it would be necessary to mask them out in order to extract their lengths. Since masking is needed anyway to extract the type codes of other descriptors, it is more efficient to relegate the flags to them.
- 4.9 The basic approach to designing one-word descriptors is to have them point to intermediate data that otherwise would be contained in two-word descriptors. In the simplest form, one-word descriptors would point to two-word blocks corresponding to two-word descriptors (Hanson 1980).
- 5.1 If Icon is implemented on a computer whose collating sequence is different from ASCII, such as EBCDIC, it still uses the ASCII collating sequence for comparison and sorting. Consequently, these operations may produce results that are different from ones that are expected in an EBCDIC environment. If the native character set of a computer is smaller than 256, there may be problems implementing Icon, since the size of a C char may be less than expected in some routines.
- 5.4 Even if a newly created string exists in string space, the code to find it would be complex and the time required probably would outweigh any advantages of avoiding duplicate allocation. Furthermore, the new string must be constructed somewhere first in order to know what to look for. This construction often is most conveniently performed in allocated string space, so most of the work is done already.
- 5.7 If the context in which a subscripting expression is used can be determined by the translator, different virtual machine instructions could be generated for the different contexts. If the context is dereferencing, a virtual machine instruction for producing a substring could be used to avoid the construction of a substring trapped variable and the allocation of space that might have to be reclaimed during garbage collection. Similarly, if the context is assignment, virtual machine instructions for the appropriate concatenation could be produced.
- 5.10 The following procedure illustrates the usefulness of polymorphic subscripting:

```

procedure shuffle(x)
    every lx := ?x
    return x
end

```

This procedure can shuffle strings, lists, and records. Note that subscripting is implicit in the element-generation and random-selection operations. The same principle applies to explicit subscripting, however.

6.2 An empty list consists of a list-header block and one list-element block. For convenience in diagramming, the list-element blocks in Chapter 6 have space for only four elements, but the normal number is eight. Therefore, on a computer with 32-bit words, a list-element block occupies 100 bytes, while a list-header block occupies 24 bytes. Thus, on a computer with 32-bit words, an empty list occupies 124 bytes in all. On a computer with 16-bit words, the empty list is half this big. This may seem like a lot of space for "nothing," but an empty list usually is created so that elements can be added to it, in which case the overhead becomes progressively less significant.

6.4 Just because a list element is removed from a list by a stack or queue operation does not mean that the element is inaccessible. Consider the expression

`process(a[1], pop(a))`

Since the arguments are not dereferenced until both of them are evaluated, it might prove surprising if the value of `a[1]` were changed by the `pop`. Although such situations are unlikely in practice, it is important that list accesses behave coherently and consistently. One way to view the handling of this situation is that the `pop` does not remove an element but only makes it unavailable for *subsequent* access.

6.5 As indicated by the preceding solution, references to list elements that are removed by stack or queue operations may remain. It is easy to construct examples in which there are such references to unlinked list-element blocks.

7.3 An empty set consists of just a set-header block. There are two words for the title and size. A computer with 16-bit words has thirteen 4-byte slots, while a computer with 32-bit words has thirty-seven 8-byte slots. Thus, on a computer with 16-bit words, an empty set occupies 56 bytes, while on a computer with 32-bit words, an empty set occupies 304 bytes. Each member added to a set occupies 12 bytes on a computer with 16-bit words and 24 bytes on a computer with 32-bit words.

7.8 It is necessary to access a table to determine whether an element is already in it. Since the table contains the default value, it is readily available when it is needed. Because the default value may not be needed, it is not worth the trouble always to put it in table-element trapped-variable blocks.

7.12 The default value of a table is constant and could be used for computing its hash number.

7.13 If hashing is based on an attribute of a value that can change, two hash computations on that value may produce different results. If this happens, the value appears to be different in the two cases. Thus, the same value might be inserted in a set twice, an element that is in a table might not be found, and so on.

8.1 The `str` instruction pushes a descriptor on the interpreter stack. The `d`-word of this descriptor is the string length, and the `v`-word is a pointer to its location. Since the interpreter stack grows toward increasing memory addresses, it is natural and convenient to push the `v`-word first and to have its value as the first operand of the `str` instruction.

8.3 The two expressions

$$a[?i] := a[?i] + 1$$

and

$$a[?i] += 1$$

generally produce different results.

8.4 A new operator requires new syntax, which must be handled in the translator. Since each operator has its own virtual machine instruction, a new instruction must be added for the new operator. The translator, linker, and run-time system all must handle this new virtual machine instruction. In the run-time system, the code for this instruction must be added to the main switch statement in the interpreter, with an appropriate call to a C routine to implement the operation.

9.2 Suspension of functions and operations (but not procedures) increases the interpreter level. This occurs both in nested generators and generators in mutual evaluation. Thus, if  $expr_i$  is a function or operator that suspends, the interpreter level is increased by its evaluation in both

$$expr_2(expr_1)$$

and

$$expr_1 \ \& \ expr_2$$

9.5 Exercise 2.3 contains an example of a "black hole" as a result of repeated alternation.

9.7 If the result of  $expr_1$  in

$$\text{every } expr_1 \text{ do } expr_2$$

is not popped, the interpreter stack builds up for every value produced by  $expr_1$ . While these descriptors are removed when the loop terminates, interpreter stack overflow would result in expressions like

$$\text{every } 1 \text{ to } 100000 \text{ do } expr_2$$

## 9.8 The expressions

`every expr1`

and

`expr1 & &fail`

are equivalent unless `expr1` contains a `break` or `next` expression.

- 10.1 If a procedure or function call contains an extra argument that fails, the call is not performed (more accurately, the previous argument is resumed).
- 10.3 If a variable whose value is on the interpreter stack is returned from a procedure, the variable must be dereferenced, since the value on the stack may be overwritten. Thus, arguments and dynamic local identifiers are dereferenced on procedure return. Static local identifiers are not dereferenced, since they are not on the stack. There is a good argument why static local identifiers should be dereferenced, since local identifiers are expected to be accessible only within the procedures in which they are declared. Suspension also dereferences variables whose values are on the stack. These values will not be overwritten, however, since the portion of the stack containing these values is not removed until the surrounding expression frame is removed, at which time the variables in it are no longer accessible. The rationale for dereferencing on suspension is that there should be no difference, at the source-language call, between a procedure that returns and a procedure that suspends. Furthermore, if dereferencing on suspension were not done, the arguments and local identifiers of the suspending procedure could be modified by the procedure that calls it. This would violate the semantic concept of "local," although, as mentioned previously, static local identifiers are not dereferenced. This may be viewed as a bug.
- 10.4 The interpreter stack grows upward, regardless of the architecture of the computer on which Icon is implemented. On a computer with an upward-growing C stack, the C stack base is in the middle of the co-expression block, instead of at its end. There is an advantage, in co-expressions, to having a downward-growing C stack: the interpreter and C stacks grow toward each other, sharing space, and run out of space only when they collide. For an upward-growing C stack, either the interpreter stack or the C stack may run out of space, even if there is unused space in the other.
- 11.1 Having the type code in the d-word of a descriptor allows its type to be determined without a level of indirection to the block title through its v-word.
- 11.2 *Answer removed: the question no longer applies.*
- 11.3 The values of global and static identifiers are in the icode region, so any assignment to one of them changes data in the icode region.

- 11.4 Global and static identifiers could be in a single array in the icode region. It is simply more convenient to handle them separately in the translator and linker.
- 11.5 The names of global identifiers are needed for the display function and for the string invocation of functions as described in Exercise 10.2.
- 11.6 The names of static identifiers are in their procedure blocks.
- 11.17 The maximum type code is a small integer. Therefore, it is only necessary that the allocated block region be at an address larger than this value. This happens automatically because of the way the code for the run-time system is arranged, although it would be trivially easy to force.
- 11.19 If there were more than one pointer on quallist to the same qualifier, the v-word of that qualifier would be relocated more than once, with an erroneous result. Such an error would show up when the qualifier was used in subsequent program execution after garbage collection.
- 11.21 *Answer removed: the question no longer applies.*
- 11.26 Recursion in markblock occurs when a block contains a pointer to another block. Thus, pointer chains cause recursion of corresponding depth. The following program builds a linked list whose length is the number of lines in the input file:

```

record lines(value, nextl)

procedure main()
  head := lines()
  current := head
  while current.value := read() do {
    current.nextl := lines()
    current := current.nextl
  }
  :
end

```

In the case of a garbage collection, the depth of recursion in markblock is the length of the linked list.

- 11.31 An excessively large predictive need request may trigger a garbage collection unnecessarily or possibly cause error termination if there is not enough memory, although this is unlikely unless the request is enormous. If the request is satisfied, execution continues normally. If a predictive need request is less than the amount subsequently allocated and there is not enough space in the region to satisfy the allocation request, the allocation routine terminates program execution with a message indicating that there is an error in the implementation of Icon.
- 11.32 As indicated in the solution to Exercise 6.5, an unlinked list-element block may still be referenced by a variable. As long as this is the case, the list-element block cannot be reclaimed by garbage collection. In general, as long as there is a pointer to a block that is reachable from the basis, the block cannot be reclaimed.
- 11.33 A variable could point to the head of the block, with an offset referred to the location of the corresponding value. The advantage of having a variable point directly to its value is efficiency during expression evaluation. Access to variables in blocks is presumably more frequent during expression evaluation than during garbage collection. There can be at most one access to such a variable during a garbage collection, while the variable may be accessed repeatedly during expression evaluation. Furthermore, many programs use such variables frequently but never require garbage collection.
- 11.38 In the case of a type, such as real, for which all blocks are the same size, a separate allocation region can be efficiently managed by a free-list mechanism. No relocation is needed in such a region, and since all blocks are of the same size, there is no problem with fragmentation. Having many allocation regions complicates the storage-management system, of course. The implementation of an early version of Icon employed several regions in which the space for freed blocks was reused (Hanson 1980).
- 11.39 It is not possible to determine, in general, if storage is needed only temporarily or if it must be retained for an arbitrarily long time. For example, in
- `while process(read)`
- the retention of storage for input strings depends entirely on what process does. If it just writes out its argument, as shown in the exercise, storage for the strings produced by read would not have to be allocated. If, on the other hand, it pushes its argument on a list, the strings must be allocated. Since allocation is fast and garbage collection has little work to do for space that is not accessible, storage throughput has a comparatively small impact on performance.
- 12.2 On computers with 16-bit words, tests for the two types of integers must be made in all situations where type checking and conversion are performed. Furthermore, all computations that may produce a source-language integer that requires more than 16 bits must provide for

the creation of long-integer blocks. Since integers occur in many contexts, a substantial amount of code is required to handle the two types of integers.

- 12.4 The value of `MaxCvtLen` must be sufficient to handle a string whose length is the size of the character set. Thus, if Icon had 512 different characters, `MaxCvtLen` would have to be 512. Even if the number of different characters were small, it is unlikely that some other type of conversion, such as real-to-string, would dominate.

12.14 *Answer removed: the question no longer applies.*

# Appendix G

## The RTL Run-Time Language

This appendix contains a description of the language used to implement the run-time operations of the Icon compiler system. Chapter 5 provides a description of the design goals of the implementation language and an introduction to it. Some of the design decisions for the language were motivated by optimizations planned for the future, such as constant folding of csets. The use of these features is presented as if the optimizations were implemented; this insures that the optimizations will be supported by the run-time system when they are implemented. This appendix is adapted from the reference manual for the language [.ipd79.].

The translator for the implementation language is the program rtt. An rtt input file may contain operation definitions written in the implementation language, along with C definitions and declarations. Rtt has a built-in C preprocessor based on the ANSI C Standard, but with extensions to support multi-line macros with embedded preprocessor directives [.ipd65.]. Rtt prepends a standard include file, grttin.h, on the front of every implementation language file it translates.

The first part of this appendix describes the operation definitions. C language documentation should be consulted for ordinary C grammar. The extensions to ordinary C grammar are described in the latter part of the appendix.

The grammar for the implementation language is presented in extended BNF notation. Terminal symbols are set in Helvetica. Non-terminals and meta-symbols are set in *Times-Italic*. In addition to the usual meta-symbols, ::= for “is defined as” and | for “alternatives”, brackets around a sequence of symbols indicates that the sequence is optional, braces around a sequence of symbols followed by an asterisk indicates that the sequence may be repeated zero or more times, and braces followed by a plus indicates that the enclosed sequence may be repeated one or more times.

### G.1 Operation Documentation

An operation definition can be preceded by an optional description in the form of a C string literal.

*documented-definition ::= [ C-string-literal ] operation-definition*

The use of a C string allows an implementation file to be run through the C preprocessor without altering the description. The preprocessor concatenates adjacent string literals, allowing a multi-line description to be written using multiple strings. Alternatively, a multi-line description can be written using `` for line continuation. This description is stored in the operation data base where it can be extracted by documentation generation programs. These documentation generators produce formatted documentation for Icon programmers and for C programmers maintaining the Icon implementation. The documentation generators are responsible for inserting newline characters at reasonable points when printing the description.

## G.2 Types of Operations

Rtt can be used to define the built-in functions, operators, and keywords of the Icon language. (Note that there are some Icon constructs that fall outside this implementation specification system. These include control structures such as string scanning and limitation, along with record constructors and field references.)

```

operation-definition ::=
    function result-seq identifier ( [ param-list ] ) [ declare ] actions end |
    operator result-seq op identifier ( [ param-list ] ) [ declare ] actions end |
    keyword result-seq identifier actions end |
    keyword result-seq identifier const key-const end
result-seq ::= { length , length [ + ] } |
             { length [ + ] } |
             { }
length ::= integer | *
```

*result-seq* indicates the minimum and maximum length of the result sequence of an operation (the operation is treated as if it is used in a context where it produces all of its results). For example, addition always produces one result so its *result-seq* is {1, 1}. If the minimum and maximum are the same, only one number need be given, so the *result-seq* for addition can be coded as {1}. A conditional operation can produce either no results (that is, it can fail) or it can produce one result, so its *result-seq* is {0, 1}. A length of indicates unbounded, so the *result-seq* of ! is indicated by {0, }. An in the lower bound means the same thing as 0, so {0, } can be written as {, }, which simplifies to {}. A *result-seq* of {} indicates no result sequence. This is not the same as a zero-length result sequence, {0}; an operation with no result sequence does not even fail. exit is an example of such an operation.

A + following the length(s) in a *result-seq* indicates that the operation can be resumed to perform some side effect after producing its last result. All existing examples of such operations produce at most one result, performing a side effect in the process. The side effect on resumption is simply an undoing of the original side effect. An example of this is tab, which changes &pos as

the side effect.

For functions and keywords, *identifier* is the name by which the operation is known within the Icon language (for keywords, *identifier* does not include the &). New functions and keywords can be added to the language by simply translating implementations for them. For operations, *op* is (usually) the symbol by which the operation is known within the Icon language and *identifier* is a descriptive name. It is possible to have more than one operation with the same *op* as long as they have different identifiers and take a different number of operands. In addition to translating the implementation for an operator, adding a new operator requires updating iconc's lexical analyzer and parser to know about the symbol (in reality, an *operator* definition may be used for operations with non-operator syntax, in which case any syntax may be used; iconc's code generator identifies the operation by the type of node put in the parse tree by a parser action). In all cases, the *identifier* is used to construct the name(s) of the C function(s) which implement the operation.

A *param-list* is a comma separated list of parameter declarations. Some operations, such as the write function, take a variable number of arguments. This is indicated by appending a pair of brackets enclosing an identifier to the last parameter declaration. This last parameter is then an array containing the *tail* of the argument list, that is, those arguments not taken up by the preceding parameters. The identifier in brackets represents the length of the tail and has a type of C integer.

*param-list* ::= *param* { , *param* } [ [ *identifier* ] ]

Most operations need their arguments dereferenced. However, some operations, such as assignment, need undereferenced arguments and a few need both dereferenced and undereferenced versions of an argument. There are forms of parameter declarations to match each of these needs.

*param* ::= *identifier* |  
           *underef identifier* |  
           *underef identifier -> identifier*

A simple identifier indicates a dereferenced parameter. *underef* indicates an undereferenced parameter. In the third form of parameter declaration, the first identifier represents the undereferenced form of the argument and the second identifier represents the dereferenced form. This third form of declaration may not be used with the variable part of an argument list. These identifiers are of type *descriptor*. Descriptors are implemented as C structs. See Chapter 4 for a detailed explanation of descriptors. Examples of operation headers:

```
detab(s,i,...) - replace tabs with spaces, with stops at columns indicated.
function{1} detab(s, i[n])
  actions
end
```

*x <-> y* -swap values of *x* and *y*.

Reverses swap if resumed.

```
operator{0,1+} <-> rswap(underef x -> dx, underef y -> dy)
declare
```

```

    actions
end

&fail -just fail
keyword{0} fail
    actions
end

```

### G.3 Declare Clause

Some operations need C declarations that are common to several actions. These can be declared within the declare clause.

*declare ::= declare { C declarations }*

These may include *tended* declarations, which are explained below in the section on extensions to C. If a declaration can be made local to a block of embedded C code, it is usually better to put it there than in a declare clause. This is explained below in the discussion of the body action.

#### Constant Keywords

Any keyword can be implemented using general *actions*. However, for constant keywords, *iconc* can sometimes produce more efficient code if it treats the keyword as a literal constant. Therefore, a special declaration is available for declaring keywords that can be represented as Icon literals. The constant is introduced with the word *const* and can be one of four literal types.

*key-const ::= string-literal | cset-literal | integer-literal | real-literal*

When using this mechanism, it is important to be aware of the fact that *rtt* tokenizes these literals as C literals, not as Icon literals. The contents of string literals and character literals (used to represent *cset* literals) are not interpreted by *rtt* except for certain situations in string concatenation (see [ipd65.]). They are simply stored, as is, in the data base. This means that literals with escape sequences can be used even when C and Icon would give them different interpretations. However, C does not recognize control escapes, so `'''`, which is a valid Icon literal, will result in an error message from *rtt*, because the second quote ends the literal, leaving the third quote dangling. Only decimal integer literals are allowed.

### G.4 Actions

All operations other than constant keywords are implemented with general *actions*.

Actions fall into four categories: type checking and conversions, detail code expressed in extended C, abstract type computations, and error reporting.

*actions ::= { action }\**  
*action ::= checking-conversions |*

```

detail-code |
abstract { type-computations } |
runerr( msg_number [ , descriptor ] ) [ ; ]
{ actions }

```

## G.4.1 Type Checking and Conversions

The type checking and conversions are

```

checking-conversions ::= if type-check then action |
                        if type-check then action else action |
                        type_case descriptor of { { type-select }+ } |
                        len_case identifier of { { integer : action }+ default : action }
type-select ::= { type-name : }+ action |
              default : action

```

These actions specify run-time operations. These operations could be performed in C, but specifying them in the implementation language gives the compiler information it can use to generate better code.

The if actions use the result of a *type-check* expression to select an action. The *type\_case* action selects an action based on the type of a descriptor. If a *type\_case* action contains a default clause, it must be last. *type-select* clauses must be mutually exclusive in their selection. The *len\_case* action selects an action based on the length of the variable part of the argument list of the operation. The *identifier* in this action must be the one representing that length.

A *type-check* can succeed or fail. It is either an assertion of the type of a descriptor, a conversion of the type of a descriptor, or a logical expression involving *type-checks*. Only limited forms of logical expressions are supported.

```

type-check ::= simple-check { && simple-check }* |
              ! simple-check

simple-check ::= is: type-name ( descriptor ) |
               cnv: dest-type ( source [ , destination ] ) |
               def: dest-type ( source , value [ , destination ] )

dest-type ::= cset |
             integer |
             real |
             string |
             C_integer |
             C_double |
             C_string |

```

```

(exact)integer |
(exact)C_integer |
tmp_string |
tmp_cset

```

The check succeeds if the value of the descriptor is in the type indicated by *type-name*. Conversions indicated by *cnv* are the conversions between the Icon types of *cset*, *integer*, *real*, and *string*. Conversions indicated by *def* are the same conversions with a default value to be used if the original value is null.

*dest-type* is the type to which a value is to be converted, if possible. *cset*, *integer*, *real*, and *string* constitute a subset of *icon-type* which is in turn a subset of *type-name* (see below). *C\_integer*, *C\_string*, and *C\_double* are conversions to internal C types that are easier to manipulate than descriptors. Each of these types corresponds to an Icon type. A conversion to an internal C type succeeds for the same values that a conversion to the corresponding Icon type succeeds. *C\_integer* represents the C integer type used for integer values in the particular Icon implementation being compiled (typically, a 32-bit integer type). *C\_double* represents the C double type. *C\_string* represents a pointer to a null-terminated C character array. However, see below for a discussion of the destination for conversion to *C\_string*. (exact) before *integer* or *C\_integer* disallows conversions from *reals* or *strings* representing *reals*, that is, the conversion fails if the value being converted represents a real value.

Conversion to *tmp\_string* is the same as conversion to *string* (the result is a descriptor), except that the string is only guaranteed to exist for the lifetime of the operation (the lifetime of a suspended operation extends until it can no longer be resumed). Conversion to *tmp\_string* is generally less expensive than conversion to *string* and is never more expensive, but the resulting string must not be exported from the operation. *tmp\_cset* is analogous to *tmp\_string*.

The source of the conversion is the descriptor whose value is to be converted. If no destination is specified, the conversion is done ``in-place''. However, it may not actually be possible to do an argument conversion in the argument's original location, so the argument may be copied to another location as part of the conversion. Within the *scope* of the conversion, the parameter name refers to this new location. The scope of a conversion is usually only important for conversions to C types; the run-time system translator and the Icon compiler try to keep the movement of descriptor parameters transparent (see below for more details). All elements of the variable part of an argument list must be descriptors. Therefore, when an element is converted to a C type, an explicit location must be given for the destination.

The destinations for conversions to *cset*, *integer*, *real*, *string*, (exact)*integer*, *tmp\_string*, and *tmp\_cset* must be descriptors. The destinations for conversions to *C\_integer*, *C\_double*, and (exact)*C\_integer* must be the corresponding C types. However, the destination for conversion to *C\_string* must be tended. If the destination is declared as ``tended char'', then the *dword* (string length) of the tended location will be set, but the operation will not have direct access to it. The variable will look like a ``char''. Because the operation does not have access to the string length,

it is not a good idea to change the pointer once it has been set by the conversion. If the destination is declared as a descriptor, the operation has access to both the pointer to the string and the string's length (which includes the terminating null character). If a parameter is converted to C\_string and no explicit destination is given, the parameter will behave like a ``tended char '' within the scope of the conversion.

The second argument to the def conversion is the default value. The default value may be any C expression that evaluates to the correct type. These types are given in the following chart.

cset:	struct b_cset
integer:	C_integer
real:	double
string:	struct descrip
C_integer:	C_integer
C_double:	double
C_string:	char *
tmp_string:	struct descrip
tmp_cset:	struct b_cset
(exact)integer:	C_integer
(exact)C_integer:	C_integer

The numeric operators provide good examples of how conversions are used:

```
operator{1} / divide(x, y)
  if cnv:(exact)C_integer(x) && cnv:(exact)C_integer(y) then
    actions
  else {
    if !cnv:C_double(x) then
      runerr(102, x)
    if !cnv:C_double(y) then
      runerr(102, y)
    actions
  }
end
```

Within the code indicated by *actions*, x and y refer to C values rather than to the Icon descriptors of the unconverted parameters.

The subject of any type check or type conversion must be an unmodified parameter. For example, once an in-place conversion has been applied to a parameter, another conversion may not be applied to the same parameter. This helps insure that type computations in iconc only involve the unmodified types of arguments, simplifying those computations. This restriction does not apply to type checking and conversions in C code.

## G.4.2 Scope of Conversions

The following discussion is included mostly for completeness. The scope of conversions sounds complicated, but in practice problems seldom occur in code that “looks reasonable”. If a problem does occur, the translator catches it. Normally, the intricacies of scope should be ignored and the person writing run-time routines should code conversions in a manner that seems natural.

An “in-place” conversion of a parameter can create a scope for the parameter name separate from the one introduced by the parameter list. This is because conversions to C types may require the converted value to be placed in a different location with a different type. The parameter name is then associated with this new location. The original scope of a parameter starts at the beginning of the operation’s definition. The scope of a conversion starts at the conversion. A scope extends through all code that may be executed after the scope’s beginning, up to a runerr or a conversion that hides the previous scope (because the type checking portion of the implementation language does not contain loops or arbitrary gotos, scope can easily be determined lexically).

The use of an in-place conversion in the first sub-expression of a conjunction, *cnv1* && *cnv2*, has a potential for causing problems. In general, there is no way to know whether the first conversion will effectively be undone when the second conversion fails. If the first conversion is actually done in-place, the parameter name refers to the same location in both the success and failure scope of the conjunction, so the conversion is not undone. If the conversion is done into a separate location, the failure scope will refer to the original value, so the conversion will effectively be undone. Whether the conversion is actually done in-place depends on the context in which operation is used. However, conversion to C\_integer and C\_double always preserve the original value, so there is no potential problem using them as the first argument to a conjunction, nor is there any problem using a non-conversion test there. An example of this uncertainty:

```
if cnv:string(s1) && cnv:string(s2) then {
    /* s1 and s2 both refer to converted values */
}
else { /* s2 refers to the original value. s1 may
       refer to either the original or the converted value */
}
```

The translator issues a warning if there is a potential problem.

It is possible for scopes to overlap; this happens because scopes start within conditional actions. In rare instances, executable code using the name may appear within this overlapping scope, as in

the following example, which resembles code that might be found in the definition of a string analysis function such as `find`.

```

    if is:null(s) then {
        if !def:C_integer(i, k_pos) then
            runerr(101, i)
        }
    else {
        if !def:C_integer(i, 1) then
            runerr(101, i)
        }
    }
    actions

```

Here, *actions* occurs within the scope of both conversions. Note that *actions* is not in the scope of the original parameter *i*. This is because that scope is ended in each branch of the outer if by the conversions and the runerrs.

If overlap does occur, the translator tries to insure that the same location is used for the name in each scope. The only situation when it cannot do this is when the type of the location is different in each scope, for instance, one is a `C_integer` and the other is a `C_real`. If a name is referenced when there is conflicting scope, the translator issues an error message.

### G.4.3 Type Names

The *type-names* represent types of Icon intermediate values, including variable references. These are the values that enter and leave an operation; “types” internal to data structures, such as list element blocks, are handled completely within the C code.

```

type-name ::= empty_type |
            icon-type |
            variable-ref
icon-type ::= null |
            string |
            cset |
            integer |
            real |
            file |
            list |
            set |
            table |
            record |
            procedure |
            co_expression
variable-ref ::= variable |

```

```

tvsubs |
tvtbl |
kywdint |
kywdpos |
kywdsubj

```

The *type-names* are not limited to the first-class types of Icon's language definition. The *type-names* that do not follow directly from Icon types need further explanation. `empty_type` is the type containing no values and is needed for conveying certain information to the type inferencing system, such as an unreachable state. For example, the result type of `stop` is `empty_type`. It may also be used as the internal type of an empty structure. Contrast this with `null`, which consists of the null value.

Variable references are not first-class values in Icon; they cannot be assigned to variables. However, they do appear in the definition of Icon as arguments to assignments and as the subject of dereferencing. For example, the semantics of the expression

```
s[3] := s
```

can be described in terms of a substring trapped variable and a simple variable reference. For this reason, it is necessary to include these references in the type system of the implementation language. `variable` consists of all variable references. It contains five distinguished subtypes. `tvsubs` contains all substring trapped variables. `tvtbl` contains all table-element trapped variables. `kywdint` contains `&random` and `&trace`. `kywdpos` contains `&pos`. `kywdsubj` contains `&subject`.

#### G.4.4 Including C Code

As noted above, C declarations can be included in a `declare` clause. Embedded C code may reference these declarations as well as declarations global to the operation.

Executable C code can be included using one of two actions.

```

detail-code ::= body { extended-C } |
               inline { extended-C }

```

`body` and `inline` are similar to each other, except that `inline` indicates code that is reasonable for the compiler to put in-line when it can. `body` indicates that for the in-line version of the operation, this piece of C code should be put in a separate function in the link library and the `body` action should be replaced by a call to that function. Any parameters or variables from the `declare` clause needed by the function must be passed as arguments to the function. Therefore, it is more efficient to declare variables needed by a `body` action within that `body` than within the `declare`. However, the scope of these local variables is limited to the `body` action.

Most Icon keywords provide examples of operations that should be generated in-line. In the following example, `nulldesc` is a global variable of type descriptor. It is defined in the include files automatically included by `rtt`.

```
&null - the null value.
```

```

keyword{1} null
  abstract {
    return null
  }
  inline {
    return nulldesc;
  }
end

```

### G.4.5 Error Reporting

`runerr( msg_number [ , descriptor ] ) [ ; ]`

`runerr` is translated into a call to the run-time error handling routine. Specifying this as a separate action rather than a C expression within a body or inline action gives the compiler additional information about the behavior of the operation. *msg\_number* is the number used to look up the error message in a run-time error table. If a descriptor is given, it is taken to be the offending value.

### G.4.6 Abstract Type Computations

`abstract { type-computations }`

The behavior of an operation with respect to types is a simplification of the full semantics of the operation. For example, the semantics of the function image is to produce the string representing its operand; its behavior in the type realm is described as simply returning some string. In general, a good simplification of an operation is too complicated to be automatically produced from the operation's implementation (of course, it is always possible to conclude that an operation can produce any type and can have any side effect, but that is hardly useful). For this reason, the programmer must use the abstract action to specify *type-computations*.

*type-computations* ::= { *store* [ *type* ] = *type* [ ; ] } [ *return type* [ ; ] ]

*type-computations* consist of side effects and a statement of the result type of the operation. There must be exactly one return *type* along any path from the start of the operation to C code containing a return, suspend, or fail.

A side effect is represented as an assignment to the *store*. The store is analogous to program memory. Program memory is made up of locations containing values. The store is made up of locations containing types. A type represents a set of values, though only certain such sets correspond to types for the purpose of abstract type computations. Types may be basic types such as all Icon integers, or they may be composite types such as all Icon integers combined with all Icon strings. The rules for specifying types are given below. A location in the store may correspond to one location in program memory, or it may correspond to several or even an unbounded number of

locations in program memory. The contents of a location in the store can be thought of as a conservative (that is, possibly overestimated) summary of values that might appear in the corresponding location(s) in program memory at run time.

Program memory can be accessed through a pointer. Similarly, the store can be indexed by a pointer type, using an expression of the form `store[type]`, to get at a given location. An Icon global variable has a location in program memory, and a reference to such a variable in an Icon program is treated as a pointer to that location. Similarly, an Icon global variable has a location in the store and, during type inferencing, a reference to the variable is interpreted as a pointer type indexing that location in the store. Because types can be composite, indexing into the store with a pointer type may actually index several locations. Suppose we have the following side effect

`store[ type1 ] = type2`

Suppose during type inferencing *type1* evaluates to a composite pointer type consisting of the pointer types for several global variables, then all corresponding locations in the store will be updated. If the above side effect is coded in the assignment operator, this situation might result from an Icon expression such as

`every (x | y) := &null`

In this example, it is obvious that both variables are changed to the null type. However, type inferencing can only deduce that at least one variable in the set is changed. Thus, it must assume that each could either be changed or left as is. It is only when the left hand side of the side effect represents a unique program variable that type inferencing knows that the variable cannot be left as is. In the current implementation of type inferencing, assignment to a single named variable is the only side effect where type inferencing recognizes that the side effect will definitely occur.

Indexing into the store with a non-pointer type corresponds to assigning to a non-variable. Such an assignment results in error termination. Type inferencing ignores any non-pointer components in the index type; they represent execution paths that don't continue and thus contribute nothing to the types of expressions.

A type in an abstract type computation is of the form

`type ::= type-name |  
           type ( variable ) |  
           attrb-ref |  
           new type-name ( type { , type } ) |  
           store [ type ] |  
           type ++ type |  
           type ** type |  
           ( type )`

The *type(variable)* expression allows type computations to be expressed in terms of the type of an argument to an operation. This must be an unmodified argument. That is, the abstract type computation involving this expression must not be within the scope of a conversion. This restriction simplifies the computations needed to perform type inferencing.

This expression is useful in several contexts, including operations that deal with structure types. The type system for a program may have several sub-types for a structure type. The structure types are list, table, set, record, substring trapped variable, and table-element trapped variable. Each of these Icon types is a composite type within the type computations, rather than a basic type. Thus the type inferencing system may be able to determine a more accurate type for an argument than can be expressed with a *type-name*. For example, it is more accurate to use

```

    if is:list(x) then
        abstract {
            return type(x)
        }
        actions
    else
        runerr(108, x)
than it is to use
    if is:list(x) then
        abstract {
            return list
        }
        actions
    else
        runerr(108, x)

```

Structure values have internal ``structure''. Structure types also need an internal structure that summarizes the structure of the values they contain. This structure is implemented with type attributes. These attributes are referenced using dot notation:

```

attrb-ref ::= type . attrb-name
attrb-name ::= lst_elem |
               set_elem |
               key |
               tbl_elem |
               default |
               all_fields |
               str_var |
               trpd_tbl

```

Just as values internal to structure values are stored in program memory, types internal to structure types are kept in the store. An attribute is a pointer type referencing a location in the store.

A list is made up of (unnamed) variables. The `lst_elem` attribute of a list type is a type representing all the variables contained in all the lists in the type. For example, part of the code for the bang operator is as follows, where `dx` is the dereferenced operand.

```

type_case dx of {

```

```

list: {
  abstract {
    return type(dx).lst_elem
  }
  actions
}
...

```

This code fragment indicates that, if the argument to bang is in a list type, bang returns some variable from some list in that type. In the type realm, bang returns a basic pointer type.

The set\_elem attribute of a set type is similar. The locations of a set never “escape” as variables. That is, it is not possible to assign to an element of a set. This is reflected in the fact that a set\_elem is always used as the index to the store and is never assigned to another location or returned from an operation. The case in the code from bang for sets is

```

set: {
  abstract {
    return store[type(dx).set_elem]
  }
  actions
}

```

Tables types have three attributes. key references a location in the store containing the type of any possible key value in any table in the table type. tbl\_elem references a location containing the type of any possible element in any table in the table type. default references a location containing the type of any possible default value for any table in the table type. Only tbl\_elem corresponds to a variable in Icon. The others must appear as indexes into the store.

Record types are implemented with a location in the store for each field, but these locations cannot be accessed separately in the type computations of the implementation language. These are only needed separately during record creation and field reference, which are handled as special cases in the compiler. Each record type does have one attribute, all\_fields, available to type computations. It is a composite type and includes the pointer types for each of the fields.

Substring trapped variables are implemented as structures. For this reason, they need structure types to describe them. The part of the structure of interest in type inferencing is the reference to the underlying variable. This is reflected in the one attribute of these types, str\_var. It is a reference to a location in the store containing the pointer types of the underlying the variables that are “trapped”. str\_var is only used as an index into the store; it is never exported from an operation.

Similarly table-element trapped variables need structure types to implement them. They have one attribute, trpd\_tbl, referencing a location in the store containing the type of the underlying table. The key type is not kept separately in the trapped variable type; it must be immediately added to the table when a table-element trapped variable type is created. This pessimistically assumes that

the key type will eventually be put in the table, but saves an attribute in the trapped variable for the key. `trpd_tbl` is only used as an index into the store; it is never exported from an operation.

The type computation, `new`, indicates that an invocation of the operation being implemented creates a new instance of a value in the specified structure type. For example, the implementation of the `list` function is

```
function{1} list(size, initial)
  abstract {
    return new list(type(initial))
  }
  actions
end
```

The type arguments to the `new` computation specify the initial values for the *attributes* of the structure. The table type is the only one that contains multiple attributes. (Note that record constructors are created during translation and are not specified via the implementation language.) Table attributes must be given in the order: `key`, `tbl_elem`, and `default`.

In the type system for a given program, a structure type is partitioned into several sub-types (these sub-types are only distinguished during type inferencing, not at run time). One of these sub-types is allocated for every easily recognized use of an operation that creates a new value for the structure type. Thus, the following Icon program has two list sub-types: one for each invocation of `list`.

```
procedure main()
  local x

  x := list(1, list(100))
end
```

Two operations are available for combining types. Union is denoted by the operator ``++'` and intersection is denoted by the operator ``**'`. Intersection has the higher precedence. These operations interpret types as sets of values. However, because types may be infinite, these sets are treated symbolically.

## G.4.7 C Extensions

The C code included using the `declare`, `body`, and `inline` actions may contain several constructs beyond those of standard C. There are five categories of C extensions: access to interface variables, declarations, type conversions/type checks, signaling run-time errors, and return statements.

In addition to their use in the body of an operation, the conversions and checks, run-time error, and declaration extensions may be used in ordinary C functions that are put through the implementation language translator.

### G.4.8 Interface Variables

Interface variables include parameters, the identifier for length of the variable part of an argument list, and the special variable `result`. Unconverted parameters, converted parameters with Icon types, and converted parameters with the internal types `tmp_string` and `tmp_cset` are descriptors and within the C code have the type `struct descrip`. Converted parameters with the internal type of `C_integer` have some signed integer type within the C code, but exactly which C integer type varies between systems. This type has been set up using a typedef in the automatically included include file so it is available for use in declarations in C code. Converted parameters with the internal type of `C_double` have the type `double` within the C code. Converted parameters of the type `C_string` have the type `char`. The length of the variable part of a argument list has the type `int` within the C code.

`result` is a special descriptor variable. Under some circumstances it is more efficient to construct a return value in this descriptor than to use other methods. See Section 5 of the implementation language reference manual for details.

### G.4.9 Declarations

The extension to declarations consists of a new storage class specifier, `tended` (register is an example of an existing storage class specifier). Understanding its use requires some knowledge of Icon storage management. Only a brief description of storage management is given here; see the Icon implementation book for further details.

Icon values are represented by descriptors. A descriptor contains both type information and value information. For large values (everything other than integers and the null value) the descriptor only contains a pointer to the value, which resides elsewhere. When such a value is dynamically created, memory for it is allocated from one of several memory regions. Strings are allocated from the *string region*. All other relocatable values are allocated from the *block region*. The only non-relocatable values are co-expression stacks and co-expression activation blocks. On some systems non-relocatable values are allocated in the *static region*. On other systems there is no static region and these values are allocated using the C `malloc` function.

When a storage request is made to a region and there is not enough room in that region, a *garbage collection* occurs. All *reachable* values for each region are located. Values in the string and block regions are moved into a contiguous area at the bottom of the region, creating (hopefully) free space at the end of the region. Unreachable co-expression stacks and activator blocks are “freed”. The garbage collector must be able to recognize and save all values that might be referenced after the garbage collection and it must be able to find and update all pointers to the relocated values. Operation arguments that contain pointers into one of these regions can always be found by garbage collection. The implementations of many operations need other descriptors or pointers into memory regions. The `tended` storage class identifies those descriptors and pointers that may have *live* values

when a garbage collection could occur (that is, when a memory allocation is performed).

A descriptor is implemented as a C struct named `descrip`, so an example of a tended descriptor declaration is

```
tended struct descrip d;
```

Blocks are also implemented as C structs. The following list illustrates the types of block pointers that may be tended.

```
tended struct b_real *bp;
tended struct b_cset *bp;
tended struct b_file *bp;
tended struct b_proc *bp;
tended struct b_list *bp;
tended struct b_lelem *bp;
tended struct b_table *bp;
tended struct b_telem *bp;
tended struct b_set *bp;
tended struct b_selem *bp;
tended struct b_record *bp;
tended struct b_tvkywd *bp;
tended struct b_tvsubs *bp;
tended struct b_tvttl *bp;
tended struct b_refresh *bp;
tended struct b_coexpr *cp;
```

Alternatively, a union pointer can be used to tend a pointer to any kind of block.

```
tended union block *bp;
```

Character pointers may also be tended. However, garbage collection needs a length associated with a pointer into the string region. Unlike values in the block region, the strings themselves do not have a length stored with them. Garbage collection treats a tended character pointer as a zero-length string. These character pointers are almost always pointers into some string, so garbage collection effectively treats them as zero-length substrings of the strings. The string as a whole must be tended by some descriptor so that it is preserved. The purpose of tending a character pointer is to insure that the pointer is relocated with the string it points into. An example is

```
tended char *s1, *s2;
```

Tended arrays are not supported. `tended` may only be used with variables of local scope. `tended` and `register` are mutually exclusive. If no initial value is given, one is supplied that is consistent with garbage collection.

### G.4.10 Type Conversions/Type Checks

Some conditional expressions have been added to C. These are based on type checks in the type specification part of the implementation language.

```
is: type-name ( source )
cnv: dest-type ( source , destination )
def: dest-type ( source , value , destination )
```

*source* must be an Icon value, that is, a descriptor. *destination* must be a variable whose type is consistent with the conversion. These type checks may appear anywhere a conditional expression is valid in a C program. Note that *is*, *cnv*, and *def* are reserved words to distinguish them from labels.

The *type\_case* statement may be used in extended C. This statement has the same form as the corresponding action, but in this context, C code replaces the *actions* in the *type-select* clauses.

### G.4.11 Signaling Run-time Errors

*runerr* is used for signaling run-time errors. It acts like a function but may take either 1 or 2 arguments. The first argument is the error number. If the error has an associated value, the second argument is a descriptor containing that value.

### G.4.12 Return Statements

There are three statements for leaving the execution of an operation. These are analogous to the corresponding expressions in the Icon language.

```
ret-statments ::= return ret-value ; |
                suspend ret-value ; |
                fail ;
ret-value ::= descriptor |
            C_integer expression |
            C_double expression |
            C_string expression |
            descript-constructor
```

*descriptor* is an expression of type *struct descrip*. For example

```
{
  tended struct descrip dp;
  ...
  suspend dp;
  ...
}
```

Use of `C_integer`, `C_double`, or `C_string` to prefix an expression indicates that the expression evaluates to the indicated C type and not to a descriptor. When necessary, a descriptor is constructed from the result of the expression, but when possible the Icon compiler produces code that can use the raw C value (See Section 5 of the implementation language reference manual). As an example, the integer case in the divide operation is simply

```
inline {
    return C_integer x / y;
}
```

Note that a returned C string must not be in a local (dynamic) character array; it must have a global lifetime.

A *descript-constructor* is an expression that explicitly converts a pointer into a descriptor. It is only valid in a return statement, because it builds the descriptor in the implicit location of the return value.

```
descript-constructor ::= string ( length , char-ptr ) |
                        cset ( block-ptr ) |
                        real ( block-ptr ) |
                        file ( block-ptr ) |
                        procedure ( block-ptr ) |
                        list ( block-ptr ) |
                        set ( block-ptr ) |
                        record ( block-ptr ) |
                        table ( block-ptr ) |
                        co_expression ( stack-ptr ) |
                        tvtbl ( block-ptr ) |
                        named_var ( descr-ptr ) |
                        struct_var ( descr-ptr , block-ptr ) |
                        substr ( descr-ptr , start , len ) |
                        kywdint ( descr-ptr ) |
                        kywdpos ( descr-ptr ) |
                        kywdsubj ( descr-ptr )
```

The arguments to `string` are the length of the string and the pointer to the start of the string. *block-ptrs* are pointers to blocks of the corresponding types. *stack-ptr* is a pointer to a co-expression stack. *descr-ptr* is a pointer to a descriptor. `named_var` is used to create a reference to a variable (descriptor) that is not in a block. `struct_var` is used to create a reference to a variable that is in a block. The Icon garbage collector works in terms of whole blocks. It cannot preserve just a single variable in the block, so the descriptor referencing a variable must contain enough information for the garbage collector to find the start of the block. That is what the *block-ptr* is for. `substr` creates a substring trapped variable for the given descriptor, starting point within the string, and length. `kywdint`, `kywdpos`, and `kywdsubj` create references to keyword variables.

Note that returning either C\_double *expression* or substr(*descr-ptr*, *start*, *len*) may trigger a garbage collection.

# Appendix H

## Glossary of Defined Symbols

This glossary explains the `#ifdef` symbols that are used in the C-based source code of the Icon and Unicon implementation. The current version of Icon, version 9.5, has gone to extreme lengths to minimize the number of symbols in its source code. The *Where* field in the table indicates whether a symbol appears in classic Icon sources (I), in Icon 9.5 (9), and/or in Unicon.

Classic symbols are defined in `define.h` files copied over from `config/*/define.h` in various manual platform configurations. Many symbols, particularly ones beginning with `HAVE_`, are generated by `autoconf` on platforms where it is available.

The list deliberately omits symbols that are predefined on their respective compilers that begin with one or two underscores. Also omitted are event codes beginning `E_` or `e_`, which normally are integer constants but may be used as `ifdef` controls over whether individual events are instrumented within a runtime system build. Another category of omitted symbols are those that are the names of parameters in `#begdef` multi-line macros; they are local in scope and cannot be modified in `define.h` or used anywhere else.

Symbol	Where	Definition
<code>abs</code>	all	compute absolute value of x and y
<code>ActStkBkEnts</code>	all	number of entries in an activation stack block
<code>AL_SITECONFIG_H_</code>	U	protect against including openal-related stuff twice
<code>AlcMax</code>	all	this many co-expressions or higher triggers aggressive co-expression garbage collection (every new co-expression?! needs to be renamed)

ALIGN_SIZE	U	alignment chunk size (gdbm)
alloca	U	system provides alloca()
AllocReg	all	allocate a region
AllocType	U	allocation type
Arrays	U	support C-compatible integer and real arrays
_AS_HEADER	U	GNU portable shell tool, used as a header (libtp)
AsmOver	IU	use assembler code overflow checks (remove)
Audio	U	support audio file playback
BASE_H	U	base.h has been included (audio)
bcopy	IU	redefine bcopy as memcpy (libxpm; switch to memcpy)
Bell	all	ASCII control-G, probably
Big	all	number above which string-to-numeric conversion starts to get fuzzy
BinaryHeader	9	executable header is an actual binary executable, not a script
BLKSIZE	IU	standard block region size
BLOCKSIZE	IU	standard block region size
Bool	IU	Boolean data type (xpm)
BOOL	IU	Boolean data type; avoiding a double typedef
BROKEN_LIBIO	U	work around broken <libio.h>
BSD	IU	build on BSD UNIX platform
BSD_4_4_LITE	U	accommodate BSD 4.4 Lite's unusual socket sin_len/sun_len behavior
ByteBits	IU	number of bits in a byte
bzero	IU	redefine bzero as memset (libxpm; switch to memset)
CA_H	IU	ca.h has been included

CComp	IU	C compiler that iconc uses
CLK_TCK	all	clock ticks per second. deprecated, think about revising mil- lisec() implementation.
CoClean	IU	cleanup co-expressions
CoExpr	IU	support co-expressions
COEXPSIZE	IU	standard co-expression stack size
COMPILER	IU	build iconc optimizing compiler
Concurrent	U	build with concurrent threads
ConcurrentCOMPILER	U	build iconc with (preliminary) concurrency support
ConsoleWindow	U	emulate a console window (graphics, mainly Windows)
const	U	disable the const keyword when necessary
COpts	IU	C compiler command line options that iconc uses
CRAY	IU	build on Cray (gdbm, should delete)
CRAY_STACK	U	legacy CRAY stack linkage structs (delete)
CStateSize	IU	size of the C state (saved registers) for co-expressions
CSuffix	all	extension used for C source files
CUsage	IU	iconc usage string
CYGWIN	9	build on Cygwin platform
DARWIN_PBUILDER	U	enable Mac OS X support in audio code
DataParallel	U	support list-at-a-time data parallel operations
Dbm	U	enable (N)DBM database support
DBSuffix	all	extension used for runtime system database files
Debug	9	enable debugging features (libXpm)
DEBUG	U	print debugging info (delete or rename)

DebugOnly	U	output debugging statistics after type inferencing (rename)
DeBug	IU	enable debugging features
DebugHeap	U	enable extra heap debugging checks
DeBugIconx	IU	enable debugging features for the VM interpreter, iconx
DeBugLinker	IU	enable debugging features for the linker, ilink
DeBugTrans	IU	enable debugging features for the translator, itran
DEBUG_INTERP	IU	include VM interpreter debugging function stkdump()
DefPath	IU	default IPATH/LPATH (legacy, situation more complicated now)
DescriptorDouble	U	store reals in descriptors
DiffPtrs	all	difference/distance between two pointers
DL_GETERRNO	U	some FreeBSD version <= 2.0 detectable symbol (delete)
DLLICONX	U	build iconx as a .dll
DMALLOC	U	enable debugging malloc (audio)
DMAXCOLORS	IU	display's maximum number of colors, if indexed/allocated colors are in use
DosFnCs	IU	enable MS-DOS functions (should delete)
Double	all	require C double alignment
EBCDIC	IU	build on (non-ASCII) EBCDIC (old IBM) platform
errno	U	undefine errno to allow use as a Unicon keyword
EventMon	IU	support program execution event monitoring
EWOULDBLOCK	U	define socket error codes on Windows
ExecImages	IU	executable images (save() function), obsolete
ExecSuffix	all	extension used for executables
ExpTools	IU	use TOOLS environment to modify patched executables (?)

ExternalFunctions	IU	external functions; some kind of precursor to loadfunc()
F_Nqual	all	flag: descriptor value is not a string/qualifier
F_Ptr	all	flag: descriptor vword is a pointer
F_TypeCode	all	flag: descriptor dword contains a type code
F_Var	all	flag: descriptor vword is a variable reference
FAttrib	all	support file attributes
FieldTableCompression	U	Enable field table compression in icode
FILEPAT_H	IU	filepat.h has been included
FileSep	all	File path separator. Specific to common/filepart.c
FncTrace	IU	enable call tracing keyword &ftrace (delete)
FOR_MSW	IU	libXpm Microsoft Windows support
FreeBSD	IU	building on FreeBSD platform
fsync	U	provide faux fsync() on Windows if needed
GammaCorrection	all	gamma correction value to apply to colors
GenericBSD	IU	build on generic BSD-based platform
GC_TIMING_TUNING	U	measure and report garbage collection times (rename?)
_GETOPT_H	U	"getopt.h" has already been included (gdbm)
GETOPT_COMPAT	U	non-POSIX getopt() compatible (gdbm, should delete)
Global	all	embarrassing alias for "extern" (for ancient pre-ANSI compilers; delete)
GNU	U	use "ndbm.h" not <ndbm.h> (gdbm)
GranSize	IU	storage allocation granule size (dead, delete)
Graphics	all	build with (2D) graphics facilities
Graphics3D	U	build with 3D graphics facilities

HardWiredPaths	IU	support patching the path to iconx into executable headers
HAVE_ALLOCA_H	U	system has <alloca.h> (gdbm)
HAVE_ARPA_INET_H	U	system has <arpa/inet.h> (libtp)
HAVE_ASCTIME_R	U	system has asctime_r()
HAVE_BCOPY	U	system has bcopy() (libtp; switch to memcpy or memmove)
HAVE_BZERO	U	system has bzero() (libtp; switch to memset)
HAVE_CLOCK_GETTIME	U	system has clock_gettime()
HAVE_CONFIG_H	U	build library using Unicon's "config.h"
HAVE_CRYPT	U	system has crypt()
HAVE_CRYPT_R	U	system has crypt_r()
HAVE_CTIME_R	U	system has ctime_r()
HAVE_D3D	U	system has Direct3D library
HAVE_ERRNO_H	U	system has <errno.h>
HAVE_FCNTL_H	U	system has <fcntl.h>
HAVE_FILE_H	U	system has <file.h>
HAVE_FLOCK	U	system has flock()
HAVE_FSYNC	U	system has fsync()
HAVE_FTRUNCATE	U	system has ftruncate()
HAVE_GETADDRINFO	U	system has getaddrinfo()
HAVE_GETGENT_R	U	system has getgrent_r()
HAVE_GETHOSTNAME	U	system has gethostname()
HAVE_GETPWUID	U	system has getpwuid()
HAVE_GETRLIMIT	U	system has getrlimit()
HAVE_GETRUSAGE	U	system has getrusage()

HAVE_GETUID	U	system has getuid()
HAVE_GMTIME_R	U	system has gmtime_r()
HAVE_INET_ATON	U	system has inet_aton()
HAVE_INET_PTON	U	system has inet_pton()
HAVE_KEYWORD__THREAD	U	system has __thread
HAVE_LIBALUT	U	system has libalut, the openAL utility library
HAVE_LIBALTYPES	U	system has <AL/altypes.h> and <AL/alexttypes.h>
HAVE_LIBCL	U	system has libcl (opengl() function; unfinished business)
HAVE_LIBFTGL	U	system has FTGL, a font library for OpenGL
HAVE_LIBGL	U	system has OpenGL 3D library
HAVE_LIBIODBC	U	system has libiodbc
HAVE_LIBJPEG	U	system has JPEG image format
HAVE_LIBJVOIP	U	system has JVOIP
HAVE_LIBJRTP	U	system has JRTP
HAVE_LIBJTHREAD	U	system has JTHREAD
HAVE_LIBODBC	U	system has libodbc
HAVE_LIBOGG	U	system has OGG audio
HAVE_LIBOPENAL	U	system has OpenAL audio
HAVE_LIBPNG	U	system has PNG image format
HAVE_LIBPTHREAD	U	system has posix threads library
HAVE_LIBSDL	U	system has SDL
HAVE_LIBSMPEG	U	system has SMPEG library
HAVE_LIBSSL	U	system has SSL encryption
HAVE_LIBVOIP	U	system has libvoip

HAVE_LIBVORBIS	U	system has vorbis
HAVE_LIBX11	U	system has Xlib
HAVE_LIBXPM	U	system has libXpm (avoid gotchas when including xpm.h)
HAVE_LIBZ	U	system has libZ compression
HAVE_MEMCPY	U	system has memcpy()
HAVE_MEMORY_H	U	system has <memory.h>
HAVE_MEMSET	U	system has memset()
HAVE_NET_ERRNO_H	U	system has <net/errno.h>
HAVE_NETDB_H	U	system has <netdb.h>
HAVE_NETINET_IN_H	U	system has <netinet/in.h>
HAVE_OGG	U	system has libogg (merge into HAVE_LIBOGG or delete)
HAVE_RENAME	U	system has rename() (gdbm)
HAVE_SETRLIMIT	U	system has setrlimit()
HAVE_SNPRINTF	U	system has snprintf()
HAVE_ST_BLKSIZE	U	system stat() has st_blksize field
HAVE_STDLIB_H	U	system has <stdlib.h> (gdbm)
HAVE_STRERROR	U	system has strerror()
HAVE_STRING_H	U	system has <string.h>
HAVE_STRINGS_H	U	system has <strings.h>
HAVE_SYS_ERRNO_H	U	system has <sys/errno.h>
HAVE_SYS_ERRLIST	U	system has sys_errlist[]
HAVE_SYS_FILE_H	U	system has <sys/file.h>
HAVE_SYS_NERR	U	system has sys_nerr
HAVE_SYS_RESOURCE_H	U	system has <sys/resource.h>

HAVE_SYS_SOCKET_H	U	system has <sys/socket.h>
HAVE_SYS_TYPES_H	U	system has <sys/types.h>
HAVE_TIMEZONE	U	system has timezone()
HAVE_TZNAME	U	system has tzname()
HAVE_UNISTD_H	U	system has <unistd.h>
HAVE_VOICE	U	system has voice over IP
HAVE_VSPRINTF	U	system has vsprintf()
HAVE_WORKING_VFORK	U	system has a working vfork() function
HAVE_XFT	U	system has XFT library
HaveProfil	IU	system has profil(). Should be autoconfed.
HaveXpmFormat	9	Xpm support is available
Header	IU	system has an executable header of some kind
HEAPSIZE	IU	standard allocated block region size
HELPER_THREAD	U	helper thread handles window input events (pollevent() calls should be removed, not made a no-op)
HighResTime	U	use high resolution timers if tracing type inferencing
HostStr	IU	host name to use instead of what uname() would give
HP	IU	build on Hewlett Packard platform
HSegs	all	hash table segments
HSlots	all	hash table slots
HSuffix	IU	extension used for C include files
ICA_H	IU	ica.h has been included
IcodeASuffix	all	extension used for icode "a" files ? (delete)
IcodeSuffix	all	extension used for icode a files

Iconc	IU	build optimizing compiler (merge with COMPILER?)
IconcLogAllocations	U	log memory allocations in iconc
ICONCORE	IU	environment variable that says errors should coredump
ICONC_XLIB	IU	link option to link graphics into iconc-generated executable
Iconify	IU	enable canvas=iconic to actually call XIconifyWindow
IN_GCC	U	if maybe we are compiling using gcc (gdbm; consider delete)
index	all	define legacy index function as strchr (libxpm; just nuke index)
INT_16_BITS	IU	C compiler's int is 16 bits (gdbm)
IntBits	all	number of bits in an int
INTMAIN	IU	C compiler requires main to return int not void
IPATH	IU	environment variable list of directories the linker searches for ucode modules
IRIS4D	IU	build on SGI Iris platform
ISQL	U	system supports SQL/ODBC
JCS_EXTENSIONS	U	use libjpeg-turbo jpeg color space extensions
JLIB	U	building with Jori's VOIP library
KbhitIoctl	U	implement kbhit() as a call to ioctl()
KbhitPoll	U	use poll() to wait for keyboard input in lieu of kbhit()
KeyboardFnCs	all	support (raw) keyboard functions
L_SET	U	define alias for SEEK_SET (gdbm; change code to just SEEK_SET?)
LargeInts	IU	system has arbitrary precision integers
LibSuffix	IU	extension used for C (static) libraries
_LIBTP_	U	we are internal and don't need externs for methods

LineCodes	IU	support better debug/error/line number reporting
lint	IU	is the lint tool in use? (byacc parser skeleton)
Linux	U	system is running Linux
LoadFunc	all	support dynamically loaded C code via loadfunc()
LOCK_EX	U	provide a LOCK_EX definition for flock() if one is missing (gdbm)
LOCK_NB	U	provide a LOCK_NB definition for flock() if one is missing (gdbm)
LOCK_SH	U	provide a LOCK_SH definition for flock() if one is missing (gdbm)
LOCK_UN	U	provide a LOCK_UN definition for flock() if one is missing (gdbm)
LogHSlots	all	log(hash table slots)
LogHuge	all	maximum base 10 exponent (+ 1) of real/double, used to detect overflow
LONG	all	maybe it is just an int
LONG_64_BITS	IU	C compiler's long is 64 bits (gdbm)
LongLongWord	U	use long long int for typedef of word
LONG64	IU	C compiler's long is 64 bits (xpm)
LoopThreshold	U	number of tended var initializations iconc will unroll
M_PI	IU	constant value of Pi
MacGraph	U	build graphics using (legacy pre OSX) Mac graphics (should delete)
MACGRAPH_H	IU	macgraph.h has been included
MACINTOSH	all	build on legacy Mac platform (delete?)
MacOSX	U	build on modern UNIX-based Mac platform

max	all	compute maximum of x and y
MaxAbrSize	all	maximum allocated block region size
MAXADDRS	U	maximum number of IP addresses associated with a host name (libtp)
MaxBlock	all	maximum size that can be allocated via malloc()
MAXCOLORNAME	all	maximum length of a color name
MAXFONTWORD	all	maximum length of a font family name
MaxHdr	all	maximum supported size of an executable header
MaxHeader	IU	bytes offset at which the icode header will be found
MaxHLoad	all	average hash table bucket length that triggers expansion
MAXHOSTNAMELEN	U	maximum host name length (change to use HOST_NAME_MAX from <limits.h>)
MaxLevel	IU	Maximum levels (fragment, delete)
MaxListSlots	all	Maximum number of list slots per block, if any
MaxLong	all	largest long integer
MaxNegInt	all	string representation of smallest negative number
MaxPath	all	Maximum path length (merge with PATH_MAX ?)
MaxStrSpace	all	maximum allocated string region size
MAXXOBS	all	maximum number of X Windows objects per call
MDEBUG	U	Include messaging debug output to standard error (delete)
Messaging	U	build in support for HTTP, POP, etc.
MICROSOFT	U	build on legacy Microsoft C compiler (delete)
min	all	compute minimum of x and y
MinAbrSize	all	minimum allocated block region size
MinHLoad	all	average hash table bucket length that triggers reduction

MinLong	all	smallest long integer
MinMStackSize	IU	minimum main co-expression stack size
MinQualLstSize	IU	minimum qualifier list size
MinStackSize	IU	minimum stack size
MinStatSize	IU	minimum static region size (delete)
MinStrSpace	IU	minimum string region size (delete)
MonitoredTrappedvar	U	support variable traps, apparently only on locals
_MSC_VER	IU	Microsoft C version, dated workaround, check for deletion
MSDOS	IU	build on Microsoft DOS and descendants (includes Windows, LOL)
MStackSize	all	default main co-expression's interpreter stack size
MSTKSIZE	IU	environment variable to override main co-expression's stack size
MSVC	IU	build on Microsoft Windows using Visual C/C++
MSWIN	9	build on Microsoft Windows
MSWIN64	9	build on 64-bit Microsoft Windows
MSWindows	IU	build graphics using Microsoft Windows
MultipleRuns	IU	support multiple runs (e.g. ProIcon)
MultiThread	IU	support multiple loaded programs
MVS	IU	build on MVS operating system
NAME_MAX	U	longest allowed filename defaults to _POSIX_NAME_MAX
NamedSemaphores	9U	Named semaphores used on MacOS
NAMESLOWCASE	9	store (color) names in lower case (libXpm)
NativeCoswitch	U	build co-expression facilities using assembler
NativeObjects	U	support objects directly, not as records (experimental/unfinished)

NEED_STRCASECMP	9	provide strcasecmp() if needed (libXpm)
NEED_STRDUP	9	provide strdup() if needed (libXpm)
NEED_STRSTR	9	provide strstr() if needed (libXpm)
NEED_UTIME	U	include <utime.h> if needed (posix facilities)
Network	U	provide some crude web-reading code (consider deletion)
Never	U	not defined (needs examination)
NO_CONFIG_H	IU	don't use config.h build standalone (rename?)
NO_ZPIPE	IU	don't uncompress .Z files via a piped process (libXpm)
NoArrays	U	build without arrays
NoAuto	U	build without autoconf (gdbm)
NoCoExpr	IU	build without co-expressions
NoConcurrent	U	build without concurrency
NoDbm	U	build without DBM database support
NOERRBUF	IU	environment variable, if set do not buffer standard error output
NoEventMon	U	build without event monitoring
NoExternalFunctions	U	build without external functions support
NoDescriptorDouble	U	build without storing reals in descriptors
NoFreeColorFix	IU	don't free any context's colors (perma-enable the fix)
NoGL	U	build without OpenGL
NoGraphics	IU	build without graphics facilities
NoHeader	IU	build without executable headers
NoIconify	IU	build without canvas=iconic ability in graphics facilities
NoINTMAIN	IU	build without specifying that main() returns an int

NOJLIB	U	building without Jori's VOIP library
NoJPEG	U	build without JPEG
NoKeyboardFncs	all	build without keyboard functions
NoLargeInts	U	build without arbitrary precision integers
NoLIBZ	U	build without libz
NoLsExtensions	U	suppress GNU ls(1) extension on directory read
NOMAIN	IU	build patchstr as a module to be linked, omit main()
NoMessaging	U	build without messaging facilities
NoMonitoredTrappedVar	U	build without variable trap support
NoMouseWheel	IU	don't support mouse scroll wheel events (remove)
NoMultiThread	U	build without multiple loaded programs support
NoNativeCoswitch	U	build without a native co-expression switch
NoODBC	U	build without SQL/ODBC
NoPatternImage	U	build without extended pattern image() support (delete)
NoPatternType	U	build without the pattern data type
NoPipes	9	build without pipes/ open mode "p"
NoPNG	U	build without PNG
NoPosixFns	U	build without Posix facilities
NoProfil	IU	build without profil()
NoPseudoPty	U	build without pseudo-tty / bidirectional pipes
NoRandomize	U	do not set the random number seed
NoReadDirectory	9	build without directory read capability
NoRTT	all	build (preproc/) without RTT extensions
NoSrcColumnInfo	IU	build without column information

NoSrcSyntaxInfo	U	build without syntax structure information
NoStackCheck	IU	build without checks for stack overflow
NoStrInvoke	IU	build without string invocation
NoSysOpt	9	build without system getopt()
NoTypeDefs	all	grttin.h includes typedefs.h unless this symbol is defined
NoVFork	U	build without vfork()
NoWildCards	IU	build without support for asterisks in filenames
NoXpmFormat	all	build without Xpm color pixmap file format
NT	U	build on (modern) MS Windows
NTConsole	IU	build to use MS Windows native cmd.exe console
NTGCC	U	build with GCC on MS Windows
ObjSuffix	IU	extension used for C object modules
ODBCVER	U	ODBC version
OF	U	undefine OF to avoid gcc warning on redefinition
OLD_NTGCC	U	code for old versions of GCC on Windows (delete)
opt_try	U	optimization to try (need to analyze before deletion)
OptimizeDescripAsgn	U	Optimize descriptor assignments
OptimizeLit	U	Optimize literals (should perma-enable)
OptimizeLoop	U	Optimize loops (should perma-enable)
OptimizePoll	U	Optimize pollevent() calls (should perma-enable)
OVL	U	enable operator overloading (experimental; not language canon)
OVL_DEBUG	U	debug operator overloading
OsNameDefines	all	provide OS_NAME_DEFINES (libXpm)

PATH_MAX	U	maximum path length for file names (posix)
PathSep	IU	platform-dependent IPATH/LPATH separator character(s)
PatternImage	U	detailed images of (SNOBOL) pattern values (merge into PatternType)
PatternType	U	support (SNOBOL) pattern data type
Pipes	all	support (unidirectional) pipes, open() mode "p"
PIXEL_T	IU	Pixel has already been typedefed (libxpm)
PNG_LIBPNG_VER	U	portable network graphics library version
Polling	IU	include periodic checks, e.g. for Window input
PORT	IU	some vague abstract portable platform (delete)
PosixFns	U	support POSIX facilities
PPDirectives	all	preprocessor directives RTT adds to C
PPInit	IU	platform-specific predefined symbol additions
Precision	all	number of digits to use in string conversion of real number
PRINTF_DEBUG	U	enable debugging printf's for pattern facilities (rename)
PROFIL_CHAR_P	IU	profil() requires char * in its first argument
PseudoPty	U	enable pseudo-tty (bidirectional pipe-like) facilities
PTHREAD_STACK_MIN	U	Minimum thread stack size in bytes. (Pthreads)
PthreadCoswitch	U	build co-expression facilities using Pthreads
QLSIZE	IU	environment variable name to use for the size of the qualifier list (number of live strings allowed during garbage collection)
QSortFncCast	U	data type of system qsort()'s function argument
QualLstSize	all	default size of the qualifier list (no. live strings allowed during garbage collection)

ReadBinary	IU	read file in binary mode
ReadDirectory	9	support directory reading
ReadEndBinary	IU	open/update, read and write file in binary mode (rename?)
ReadText	IU	read file in text mode
ReadWriteBinary	IU	create/truncate, read and write file in binary mode
Redhat71	U	system has Redhat 7.1 header bug (Xosdefs)
RefPath	IU	default path used for includes, if any
RegionCushion	all	% of region that gc must free, or we need a bigger region
RegionGrowth	all	% of region that a new larger region should request
REPO_REVISION	U	software repository version #
reverse_logic	U	use reverse logic (delete)
rindex	IU	define legacy rindex function as strchr (libxpm; just nuke rindex)
RT_H	all	rt.h has been included
RTLD_LAZY	all	if this dload() parameter is not defined, supply a value
RttSuffix	all	extension used for RTT source files
Rttx	9	build the interpreter runtime system (rtt -x, for iconx)
RUSAGE_THREAD	U	support getrusage("thread") (Linux-specific == boo)
S_IFMT	IU	if we don't have this smybol from <sys/stat.h> include it and <sys/types.h>
S_ISDIR	IU	supply "is directory" bit flag check if its missing (Windows)
ScrollingConsoleWin	U	native editregion w/ scrollbars for console window (MS Windows)
SEEK_SET	U	define SEEK_SET as 0 if not defined (gdbm; remove)
SEPARATE_YERROR	U	don't use legacy yyerror() in error.h, use merr (delete legacy?)

sequent	all	build on Sequent platform (libXpm)
sgi	U	build on Silicon graphics platform (gdbm, should delete)
ShellHeader	IU	use a script in front of icode to launch iconx
SHORT	all	maybe it is just an int
SigFncCast	U	data type of system signal()'s function argument
_SIMX_H	IU	"simx.h" has already been included (xpm)
SM_DIGITIZER	U	Windows touchscreen device can be queried
SOCKET_ERROR	U	provide a default value of SOCKET_ERROR
SoftThreads	U	Unicon-level threads (prototype, do not use)
SourceSuffix	all	extension used for Icon/Unicon source files
sparc	U	build on Sun Sparc processor (gdbm, should delete)
SQL_LENORIND	U	data type ODBC uses for certain SQL args, usually SQLLEN
Sqline	IU	Size of qualifier list increment
SrcColumnInfo	IU	include column # information in icode
SrcSyntaxInfo	IU	include syntax information in icode
_SSL_DISC_H_	U	tpdssl.h is included (rename?)
STACK_DIRECTION	U	C stack direction (gdbm)
StackAlign	all	align interpreter stack to this many bytes
StackCheck	IU	perform interpreter stack overflow checks
StackPic	IU	diagnostic stack pictures for debugging/monitoring
StackSize	all	default size of interpreter stack
stat	U	if system idiotically defines stat, undefine it
STAT_ZFILE	IU	stat() and uncompress .Z file if needed (idiotically define stat, on Windows) (libXpm)

STDC	U	system is using ANSI C
STDC_HEADERS	U	system has ANSI standard header files
strlen	IU	if system idiotically defines strlen, undefine it
STRSIZE	IU	name of environment variable for string region size
sun	U	build on Sun Microsystems platform (gdbm, should delete)
SUN	IU	build on Sun Microsystems platform (should delete)
SVR4	9	build on UNIX System V release 4 (libXpm, gdbm)
SysOpt	all	use the system-provided getopt() instead of our own
SysSelectH	U	system has <sys/select.h> (migrate to autoconf)
SYSV	9	build on UNIX System V (libXpm)
TallyOpt	U	add -T option, print an array of 16 counters on exit (delete)
TargetDir	all	Target directory, usually the current working directory
test	IU	build a standalone test of mktemp() (rlocal, should delete)
TEST	U	build a standalone test of getopt() (gdbm, should delete)
TokDotH	9	filename that overrides the token.h file definitions to use
TP_H	U	tp.h has been included
TPDUNIX_H	U	tpdunix.h has been included
TRACE	all	name of TRACE environment variable (default: "TRACE")
TranStats	IU	generate iconc translation statistics
True	IU	non-zero (xpm)
TSTATARG	U	pass thread state arguments (experiment, do not use)
tv_bit_ge	IU	if not a macro, supply function prototype
TV_H	IU	tv.h has been included
Type	U	undefine Type to avoid gcc warning on redefinition

TypTrc	U	type tracing (iconc)
USuffix	9U	Suffix used for combined ucode files
U1Suffix	all	Suffix used for ucode instructions (may be empty)
U2Suffix	all	Suffix used for ucode public interfaces
Unicode	U	support Unicode strings and csets (prototype, do not use)
UNICON_IOCTL	U	provide a working ioctl() call (normalize to autoconf)
UNIX	IU	system is a UNIX
UNIXDISC_H	U	unixdisc.h has been included (libtp)
UpStack	IU	C stack grows upwards
URI_H	U	uri.h has been included
URI_SCHM_H	U	uri_schm.h has been included
UTIL_H	U	util.h has been included
UX10	U	HPUX 10 platforms do not get the default NAME_MAX
VOID_SPRINTF	IU	system has a void sprintf() (libXpm, delete)
VordBits	U	Number of bits in a vector word
VM	IU	build on IBM VM operating system
VMS	all	build on DEC VMS operating system
VTBL_H	IU	vtbl.h has been included
WildCards	IU	support asterisks and such in filenames
WIN32	9	Predefined compiler symbol when building on Windows
WinExtns	9	support MS Windows-specific functions
WinGraphics	9	build graphics using MS Windows (renamed from MSWindows)
WINVER	IU	MS Windows version

WOP_H	IU	wop.h has been included
WordBits	IU	number of bits in a machine word
WORD64	all	C compiler's word is 64 bits (xpm)
WriteBinary	IU	write file in binary mode
WriteText	IU	write file in text mode
X_NOT_STDC_ENV	U	under Redhat 7.1, disable this bogus definition
X_OK	IU	access() execute permission check disabled under Windows
X_WCHAR	U	under Redhat 7.1, disable this bogus definition
XlibSpecificationRelease	U	version of X11 we are compiling with
XPM_H	all	xpm.h has been included
XPMI_H	IU	XpmI.h (internal header) has been included
XpmFormat	all	build with libXpm support
XpmFree	IU	facilitate redefining libXpm's free()
_XUTIL_H_	9	xutil.h has been included
XWindows	all	build graphics using X11
YY_NO_LEAKS	IU	free up yacc stack
YYDEBUG	all	include yacc (parser) debugging code
YYLEX_PARAM	IU	send a parameter to yylex()
YYMAXDEPTH	all	initial (icon[tc]) parse stack depth (byacc, yystacksize)
YYPARSE_PARAM	IU	parameter to (icon[tc]) yyparse() (byacc)
YYPARSE_PARAM_TYPE	IU	type of parameter to (icon[tc]) yyparse() (byacc)
YYPURE	IU	free up yacc stack
YYSTACKSIZE	IU	initial (icon[tc]) parse stack depth (byacc, yymaxdepth)
YYSTYPE	all	yacc value stack type

ZPIPE	9	uncompress .Z files via a piped process (libXpm)
-------	---	--

Version 1.2, November 2002

Copyright (C) 2000,2001,2002 Free Software Foundation, Inc. 59 Temple Place, Suite 330, Boston, MA 02111-1307 USA. Everyone is permitted to copy and distribute verbatim copies of this license document, but changing it is not allowed.

## 0. PREAMBLE

The purpose of this License is to make a manual, textbook, or other functional and useful document "free" in the sense of freedom: to assure everyone the effective freedom to copy and redistribute it, with or without modifying it, either commercially or noncommercially. Secondly, this License preserves for the author and publisher a way to get credit for their work, while not being considered responsible for modifications made by others.

This License is a kind of "copyleft", which means that derivative works of the document must themselves be free in the same sense. It complements the GNU General Public License, which is a copyleft license designed for free software.

We have designed this License in order to use it for manuals for free software, because free software needs free documentation: a free program should come with manuals providing the same freedoms that the software does. But this License is not limited to software manuals; it can be used for any textual work, regardless of subject matter or whether it is published as a printed book. We recommend this License principally for works whose purpose is instruction or reference.

## 1. APPLICABILITY AND DEFINITIONS

This License applies to any manual or other work, in any medium, that contains a notice placed by the copyright holder saying it can be distributed under the terms of this License. Such a notice grants a world-wide, royalty-free license, unlimited in duration, to use that work under the conditions stated herein. The "Document", below, refers to any such manual or work. Any member of the public is a licensee, and is addressed as "you". You accept the license if you copy, modify or distribute the work in a way requiring permission under copyright law.

A "Modified Version" of the Document means any work containing the Document or a portion of it, either copied verbatim, or with modifications and/or translated into another language.

A "Secondary Section" is a named appendix or a front-matter section of the Document that deals exclusively with the relationship of the publishers or authors of the Document to the Document's overall subject (or to related matters) and contains nothing that could fall directly within that overall subject. (Thus, if the Document is in part a textbook of mathematics, a Secondary Section may not explain any mathematics.) The relationship could be a matter of historical connection with the subject or with related matters, or of legal, commercial, philosophical, ethical or political position regarding them.

The "Invariant Sections" are certain Secondary Sections whose titles are designated, as being those of Invariant Sections, in the notice that says that the Document is released under this License. If a section does not fit the above definition of Secondary then it is not allowed to be designated as

Invariant. The Document may contain zero Invariant Sections. If the Document does not identify any Invariant Sections then there are none.

The "Cover Texts" are certain short passages of text that are listed, as Front-Cover Texts or Back-Cover Texts, in the notice that says that the Document is released under this License. A Front-Cover Text may be at most 5 words, and a Back-Cover Text may be at most 25 words.

A "Transparent" copy of the Document means a machine-readable copy, represented in a format whose specification is available to the general public, that is suitable for revising the document straightforwardly with generic text editors or (for images composed of pixels) generic paint programs or (for drawings) some widely available drawing editor, and that is suitable for input to text formatters or for automatic translation to a variety of formats suitable for input to text formatters. A copy made in an otherwise Transparent file format whose markup, or absence of markup, has been arranged to thwart or discourage subsequent modification by readers is not Transparent. An image format is not Transparent if used for any substantial amount of text. A copy that is not "Transparent" is called "Opaque".

Examples of suitable formats for Transparent copies include plain ASCII without markup, Texinfo input format, LaTeX input format, SGML or XML using a publicly available DTD, and standard-conforming simple HTML, PostScript or PDF designed for human modification. Examples of transparent image formats include PNG, XCF and JPG. Opaque formats include proprietary formats that can be read and edited only by proprietary word processors, SGML or XML for which the DTD and/or processing tools are not generally available, and the machine-generated HTML, PostScript or PDF produced by some word processors for output purposes only.

The "Title Page" means, for a printed book, the title page itself, plus such following pages as are needed to hold, legibly, the material this License requires to appear in the title page. For works in formats which do not have any title page as such, "Title Page" means the text near the most prominent appearance of the work's title, preceding the beginning of the body of the text.

A section "Entitled XYZ" means a named subunit of the Document whose title either is precisely XYZ or contains XYZ in parentheses following text that translates XYZ in another language. (Here XYZ stands for a specific section name mentioned below, such as "Acknowledgements", "Dedications", "Endorsements", or "History".) To "Preserve the Title" of such a section when you modify the Document means that it remains a section "Entitled XYZ" according to this definition.

The Document may include Warranty Disclaimers next to the notice which states that this License applies to the Document. These Warranty Disclaimers are considered to be included by reference in this License, but only as regards disclaiming warranties: any other implication that these Warranty Disclaimers may have is void and has no effect on the meaning of this License.

## 2. VERBATIM COPYING

You may copy and distribute the Document in any medium, either commercially or noncommercially, provided that this License, the copyright notices, and the license notice saying this License applies to the Document are reproduced in all copies, and that you add no other conditions whatsoever to those of this License. You may not use technical measures to obstruct or control the reading

or further copying of the copies you make or distribute. However, you may accept compensation in exchange for copies. If you distribute a large enough number of copies you must also follow the conditions in section 3.

You may also lend copies, under the same conditions stated above, and you may publicly display copies.

### 3. COPYING IN QUANTITY

If you publish printed copies (or copies in media that commonly have printed covers) of the Document, numbering more than 100, and the Document's license notice requires Cover Texts, you must enclose the copies in covers that carry, clearly and legibly, all these Cover Texts: Front-Cover Texts on the front cover, and Back-Cover Texts on the back cover. Both covers must also clearly and legibly identify you as the publisher of these copies. The front cover must present the full title with all words of the title equally prominent and visible. You may add other material on the covers in addition. Copying with changes limited to the covers, as long as they preserve the title of the Document and satisfy these conditions, can be treated as verbatim copying in other respects.

If the required texts for either cover are too voluminous to fit legibly, you should put the first ones listed (as many as fit reasonably) on the actual cover, and continue the rest onto adjacent pages.

If you publish or distribute Opaque copies of the Document numbering more than 100, you must either include a machine-readable Transparent copy along with each Opaque copy, or state in or with each Opaque copy a computer-network location from which the general network-using public has access to download using public-standard network protocols a complete Transparent copy of the Document, free of added material. If you use the latter option, you must take reasonably prudent steps, when you begin distribution of Opaque copies in quantity, to ensure that this Transparent copy will remain thus accessible at the stated location until at least one year after the last time you distribute an Opaque copy (directly or through your agents or retailers) of that edition to the public.

It is requested, but not required, that you contact the authors of the Document well before redistributing any large number of copies, to give them a chance to provide you with an updated version of the Document.

### 4. MODIFICATIONS

You may copy and distribute a Modified Version of the Document under the conditions of sections 2 and 3 above, provided that you release the Modified Version under precisely this License, with the Modified Version filling the role of the Document, thus licensing distribution and modification of the Modified Version to whoever possesses a copy of it. In addition, you must do these things in the Modified Version:

A. Use in the Title Page (and on the covers, if any) a title distinct from that of the Document, and from those of previous versions (which should, if there were any, be listed in the History section of the Document). You may use the same title as a previous version if the original publisher of that version gives permission.

B. List on the Title Page, as authors, one or more persons or entities responsible for authorship

of the modifications in the Modified Version, together with at least five of the principal authors of the Document (all of its principal authors, if it has fewer than five), unless they release you from this requirement.

C. State on the Title page the name of the publisher of the Modified Version, as the publisher.

D. Preserve all the copyright notices of the Document.

E. Add an appropriate copyright notice for your modifications adjacent to the other copyright notices.

F. Include, immediately after the copyright notices, a license notice giving the public permission to use the Modified Version under the terms of this License, in the form shown in the Addendum below.

G. Preserve in that license notice the full lists of Invariant Sections and required Cover Texts given in the Document's license notice.

H. Include an unaltered copy of this License.

I. Preserve the section Entitled "History", Preserve its Title, and add to it an item stating at least the title, year, new authors, and publisher of the Modified Version as given on the Title Page. If there is no section Entitled "History" in the Document, create one stating the title, year, authors, and publisher of the Document as given on its Title Page, then add an item describing the Modified Version as stated in the previous sentence.

J. Preserve the network location, if any, given in the Document for public access to a Transparent copy of the Document, and likewise the network locations given in the Document for previous versions it was based on. These may be placed in the "History" section. You may omit a network location for a work that was published at least four years before the Document itself, or if the original publisher of the version it refers to gives permission.

K. For any section Entitled "Acknowledgements" or "Dedications", Preserve the Title of the section, and preserve in the section all the substance and tone of each of the contributor acknowledgements and/or dedications given therein.

L. Preserve all the Invariant Sections of the Document, unaltered in their text and in their titles. Section numbers or the equivalent are not considered part of the section titles.

M. Delete any section Entitled "Endorsements". Such a section may not be included in the Modified Version.

N. Do not retitle any existing section to be Entitled "Endorsements" or to conflict in title with any Invariant Section.

O. Preserve any Warranty Disclaimers.

If the Modified Version includes new front-matter sections or appendices that qualify as Secondary Sections and contain no material copied from the Document, you may at your option designate some or all of these sections as invariant. To do this, add their titles to the list of Invariant Sections in the Modified Version's license notice. These titles must be distinct from any other section titles.

You may add a section Entitled "Endorsements", provided it contains nothing but endorsements

of your Modified Version by various parties--for example, statements of peer review or that the text has been approved by an organization as the authoritative definition of a standard.

You may add a passage of up to five words as a Front-Cover Text, and a passage of up to 25 words as a Back-Cover Text, to the end of the list of Cover Texts in the Modified Version. Only one passage of Front-Cover Text and one of Back-Cover Text may be added by (or through arrangements made by) any one entity. If the Document already includes a cover text for the same cover, previously added by you or by arrangement made by the same entity you are acting on behalf of, you may not add another; but you may replace the old one, on explicit permission from the previous publisher that added the old one.

The author(s) and publisher(s) of the Document do not by this License give permission to use their names for publicity for or to assert or imply endorsement of any Modified Version.

## 5. COMBINING DOCUMENTS

You may combine the Document with other documents released under this License, under the terms defined in section 4 above for modified versions, provided that you include in the combination all of the Invariant Sections of all of the original documents, unmodified, and list them all as Invariant Sections of your combined work in its license notice, and that you preserve all their Warranty Disclaimers.

The combined work need only contain one copy of this License, and multiple identical Invariant Sections may be replaced with a single copy. If there are multiple Invariant Sections with the same name but different contents, make the title of each such section unique by adding at the end of it, in parentheses, the name of the original author or publisher of that section if known, or else a unique number. Make the same adjustment to the section titles in the list of Invariant Sections in the license notice of the combined work.

In the combination, you must combine any sections Entitled "History" in the various original documents, forming one section Entitled "History"; likewise combine any sections Entitled "Acknowledgements", and any sections Entitled "Dedications". You must delete all sections Entitled "Endorsements."

## 6. COLLECTIONS OF DOCUMENTS

You may make a collection consisting of the Document and other documents released under this License, and replace the individual copies of this License in the various documents with a single copy that is included in the collection, provided that you follow the rules of this License for verbatim copying of each of the documents in all other respects.

You may extract a single document from such a collection, and distribute it individually under this License, provided you insert a copy of this License into the extracted document, and follow this License in all other respects regarding verbatim copying of that document.

## 7. AGGREGATION WITH INDEPENDENT WORKS

A compilation of the Document or its derivatives with other separate and independent documents or works, in or on a volume of a storage or distribution medium, is called an "aggregate" if the copyright resulting from the compilation is not used to limit the legal rights of the compilation's

users beyond what the individual works permit. When the Document is included in an aggregate, this License does not apply to the other works in the aggregate which are not themselves derivative works of the Document.

If the Cover Text requirement of section 3 is applicable to these copies of the Document, then if the Document is less than one half of the entire aggregate, the Document's Cover Text may be placed on covers that bracket the Document within the aggregate, or the electronic equivalent of covers if the Document is in electronic form. Otherwise they must appear on printed covers that bracket the whole aggregate.

## 8. TRANSLATION

Translation is considered a kind of modification, so you may distribute translations of the Document under the terms of section 4. Replacing Invariant Sections with translations requires special permission from their copyright holders, but you may include translations of some or all Invariant Sections in addition to the original versions of these Invariant Sections. You may include a translation of this License, and all the license notices in the Document, and any Warranty Disclaimers, provided that you also include the original English version of this License and the original versions of those notices and disclaimers. In case of a disagreement between the translation and the original version of this License or a notice or disclaimer, the original version will prevail.

If a section in the Document is Entitled "Acknowledgements", "Dedications", or "History", the requirement (section 4) to Preserve its Title (section 1) will typically require changing the actual title.

## 9. TERMINATION

You may not copy, modify, sublicense, or distribute the Document except as expressly provided for under this License. Any other attempt to copy, modify, sublicense or distribute the Document is void, and will automatically terminate your rights under this License. However, parties who have received copies, or rights, from you under this License will not have their licenses terminated so long as such parties remain in full compliance.

## 10. FUTURE REVISIONS OF THIS LICENSE

The Free Software Foundation may publish new, revised versions of the GNU Free Documentation License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns. See <http://www.gnu.org/copyleft/>.

Each version of the License is given a distinguishing version number. If the Document specifies that a particular numbered version of this License "or any later version" applies to it, you have the option of following the terms and conditions either of that specified version or of any later version that has been published (not as a draft) by the Free Software Foundation. If the Document does not specify a version number of this License, you may choose any version ever published (not as a draft) by the Free Software Foundation.
